ABSTRACT

A catalog containing milliarcsecond-accurate positions of 1332 extragalactic radio sources distributed over the northern sky is presented – the Very Long Baseline Array Calibrator Survey (VCS1). The positions have been derived from astrometric analysis of dual-frequency 2.3 and 8.4 GHz VLBA snapshot observations; in a majority of cases, images of the sources are also available. These radio sources are suitable for use in geodetic and astrometric experiments, and as phase-reference calibrators in high-sensitivity astronomical imaging. The VCS1 is the largest high-resolution radio survey ever undertaken, and triples the number of sources available to the radio astronomy community for VLBI applications. In addition to the astrometric role, this survey can be used in active galactic nuclei, Galactic, gravitational lens and cosmological studies. The VCS1 catalog is available at http://www.nrao.edu/vlba/VCS1.

Subject headings: astrometry — radio continuum: general — reference systems — surveys — techniques: interferometric

1. Introduction

Accurate celestial and terrestrial reference frames play an important role in many areas of science. Celestial reference frames have been used historically for navigation (terrestrial and deep-space), time keeping and for studying the dynamics of solar system, Galactic and extragalactic objects. For over three decades, high-accuracy radio interferometry of extragalactic radio sources using the techniques of Very Long Baseline Interferometry (VLBI) has played a major role in defining these terrestrial and celestial frames (Sovers, Fanselow, & Jacobs 1998). Precise measurements of orientation, rotation and deformation of the Earth’s surface provides unique information concerning its internal structure, and allows detailed testing of geodynamic theories (e.g. plate tectonics) and studies of the major geophysical fluids (the atmosphere, oceans and groundwater) (Eubanks 1993).

The International Earth Rotation Service (IERS – http://www.iers.org) was established in 1988 by the International Astronomical Union (IAU) and the International Union of

\footnote{Combined Array for Research in Millimeter-wave Astronomy}
Geodesy and Geophysics (IUGG) to serve the astronomical, geodetic and geophysical communities by providing an International Celestial Reference System (ICRS) and an International Terrestrial Reference System (ITRS) to define fundamental inertial frames of reference for celestial and terrestrial positions. The current realizations of the ICRS and ITRS are the International Celestial Reference Frame (ICRF) (Ma et al. 1998) and the International Terrestrial Reference Frame (ITRF2000) (Altamimi, Sillard, and Bouchez 2002). Physical connection of these two systems depends on accurate measurement of two celestial angles (the offset in longitude and obliquity of the celestial pole with respect to its position defined by the conventional IAU precession/nutation models – $\Delta \psi$ and $\Delta \epsilon$) and three Earth orientation parameters (EOPs): UT1 (changes in the length of day due to variations in the rotation of the Earth), and the X & Y polar motion offsets.

The ICRF was adopted by the IAU as of January 1998 as the realization of the ICRS, replacing the FK5 (Fricke et al. 1988). It is a kinematic reference frame, based on the positions of distant quasars and active galactic nuclei, rather than a dynamical reference frame such as the FK5 frame (which incorporates the Earth’s motion, the mean equator and the dynamical equinox at some reference epoch). The origin of the ICRF is at the solar system barycenter, and its axes are defined by the directions to a set of extragalactic radio sources measured using VLBI. The ICRF axes are consistent with the J2000 alignment of the FK5 to within the accuracy of the FK5. The orientation of the ICRF is defined by the positions of the 212 defining sources included in the initial ICRF solution (Ma & Feissel 1997), with an estimated accuracy of 0.25 milliarcseconds (mas). A further 396 sources were included in Ma et al. (1998) as candidate ICRF sources and to improve the catalog density, and subsequently 59 additional candidate sources were presented in ICRF–Extension 1 (ICRF–Ext.1) (IERS 1999). The data used to define the ICRF included over 2.2 million VLBI observations made between 1979–1995. Significant improvement of the current ICRF will require VLBI monitoring of the mas structure of the current sources, and the addition of new sources to the frame solutions.

Astronomical imaging of weak radio sources using phase-referencing also relies on a dense and accurate grid of bright radio sources. Phase referencing (Beasley & Conway 1995) involves rapid (~minutes) antenna position-switching between an astronomical target source and an adjacent (1–5° separation) calibrator. By interpolating antenna-based phase, delay and rate corrections derived from the calibrator observations to the weak target source, phase coherence can be extended indefinitely, allowing longer integration times and thermal-noise-limited imaging. To first order, unmodeled antenna-based geometric and electronic delays are removed. Second-order errors in this process increase with (a) switching time between observations of the calibrator, which depends on antenna slew rates, source brightness and system sensitivity, and (b) the angular distance to the calibrator (i.e. a breakdown of iso-
planicity). Dense calibrator grids are required to minimize these errors. Over the past five years, phase-referencing has allowed imaging of weak radio sources including GRBs (Taylor et al. 1999), radio stars (Beasley & Güdel 2000) and deep-field radio sources (Garrett et al. 2001). Another advantage of phase referencing is the astrometric registration of multi-epoch observations, such as images of radio supernovae (Bartel et al. 2000), maser complexes (Herrnstein et al. 1999) and the Galactic center (Reid, Readhead, Vermeulen, & Treuhaft 1999).

In this paper we present the results of a multi-epoch dual-frequency Very Long Baseline Array (VLBA) survey – the VLBA Calibrator Survey (VCS1) – of 1811 VLBI sources identified on the basis of high-resolution Very Large Array observations. Some 1332 of these sources have not been previously measured in astrometric mode – their positions are presented here as the VCS1 catalog (see http://www.nrao.edu/vlba/VCS1). Future VLBA calibrator surveys (e.g. VCS2 – Fomalont et al. (2001)) will build on this initial catalog. The goals of the survey were: (a) to increase the surface density of known geodetic-grade calibrators with mas-accurate positions in the northern sky, providing candidate sources for future extensions of the ICRF; (b) to facilitate routine phase-referencing to most regions of the northern and equatorial sky, allowing high-resolution radio imaging of weak scientific targets; and (c) to provide a uniform image database at 2.3 and 8.4 GHz for use in scientific applications, including AGN & gravitational lensing studies, and cosmology. Milliarcsecond-accurate positions in the reference frame of the ICRF and a selection of dual-frequency images of VCS1 sources are presented. In Section 2 we describe the VCS1 sample and the survey observations, and present a selection of survey images. In Sections 3 & 4 we discuss the astrometric analysis of the VCS1 sample, and examine ongoing efforts to use VCS1 for science and to expand it through the Galactic Plane and to higher frequencies.

2. Data & Reduction

2.1. Observations

The VCS1 observations were carried out in ten 24-hr sessions (epochs) spanning the period August 1994 to August 1997. A description of the VLBA can be found in Napier (1994). VCS1 observations used the VLBA dual-frequency geodetic mode, observing simultaneously at 2.3 & 8.4 GHz. This is enabled by a dichroic mirror permanently positioned over the 2.3 GHz receiver, reflecting the higher frequency radiation towards a deployable reflector leading to the 8.4 GHz receiver. From each receiver four baseband frequency channels (BBCs) were recorded over a large spanned bandwidth (100 MHz at 2.3 GHz, 400 MHz at 8.4 GHz), to provide precise measurements of group delays for astrometric processing. Relevant parame-
ters for the VCS1 epochs are indicated in Table 1. For epochs 1–4 the data recording rate was 64 Mb/s; growth of the VLBA operational capabilities during 1996 allowed 128 Mb/s recording for epochs 6–10. Typical VLBA antenna system temperatures and efficiencies at 2.3 & 8.4 GHz are $\sim$30–40 K and 50%. During each epoch, typically one or two antennas exhibited poor performance due to local weather conditions.

To allow accurate imaging and position estimation, two or three 60–90 second snapshot observations of each calibrator candidate were made. The VCS1 sample was observed in declination strips, as indicated in Table 1. In each declination strip the observations were sequenced to maximize the number of VLBA antennas on source using customized scheduling software. During each epoch, six or seven periods of 30 mins were used to observe $\sim$10 geodetic–grade reference sources spanning a wide range of elevations and azimuths to assist in the astrometric processing of the survey. To schedule these reference sources, an elevation–weighted simulated annealing algorithm was developed. For a given date and time, this algorithm identifies sources visible to all VLBA antennas, generates a preferred sample spanning a wide range of antenna elevations and azimuths, giving higher weight to the outlying VLBA stations, i.e. those involving longer baselines which provide the highest astrometric accuracy. After selection, the list of reference sources is ordered in time using a simulated annealing algorithm (Press et al. 1992) to give the minimum antenna slew path through the sources, ignoring azimuth cable unwrapping.

2.2. VCS1 Sample Selection

A sample of candidate calibrators was selected from the Jodrell Bank – VLA Astrometric Survey (JVAS) (Patnaik, Browne, Wilkinson, & Wrobel 1992; Browne, Wilkinson, Patnaik, & Wrobel 1998; Wilkinson et al. 1998; Wrobel et al. 2002), an astrometric snapshot survey of compact radio sources performed with the NRAO Very Large Array during the period 1990–1993. The primary goal of JVAS was to provide phase calibrators with accurate positions for use in radio astronomy, in particular for the MERLIN array, although the survey has also been used to identify gravitationally–lensed systems, e.g. King et al. (1999). The JVAS sample was originally derived from the NRAO Green Bank 1.4 & 5 GHz surveys (Condon & Broderick 1985, 1986; Condon, Broderick, & Seielstad 1989), selecting sources with 5 GHz flux densities greater than 200 milliJansky (mJy), spectral indices $\alpha$ greater than -0.5 ($S \propto \nu^{-\alpha}$), and Galactic latitude $|b|$ greater than 2.5$^\circ$. These criteria were adopted to select bright, compact extragalactic radio sources with mas–scale core emission. The JVAS catalog contains 2118 sources in the northern hemisphere; a southern hemisphere extension of $\sim$1000 sources (0 – -30$^\circ$) is in preparation (Wrobel et al. 2002). The positional accuracy of
JVAS sources varies from 12 to 55 mas (1σ errors), depending on declination and observing conditions. The celestial frame in which the JVAS positions have been specified is not formally defined, but it appears consistent with the ICRF at the mas level. Systematic offsets due to frame alignment and/or definition are considerably smaller than the observational errors in the individual JVAS positions.

To identify a sample of calibrator candidates suitable for high–resolution applications, we selected sources from the JVAS satisfying two criteria: (a) JVAS structure estimates indicating point–like emission, suggesting compact emission on scales of 10–30 mas; and (b) 8.4 flux density ≥ 200 mJy (150 mJy in epochs 1 & 2), i.e. suitably bright for phase–referencing. An input sample of 1811 JVAS sources was selected and observed during the VCS1 epochs. The positional accuracy of the JVAS catalog is sufficient to provide initial correlation positions for VLBI purposes. We note that the VCS1 sample is a representative but not statistically–complete sample of compact flat–spectrum sources, due to incompleteness in the original JVAS survey (Patnaik, Browne, Wilkinson, & Wrobel 1992) and possible source variability since the Green Bank and JVAS surveys.

Throughout the survey, a sample of 57 bright geodetic–grade reference sources were observed to provide estimates of epoch–to–epoch and absolute positional accuracy, and to bootstrap atmospheric and instrumental error estimates for the individual epochs. All of these sources are included in the ICRF and ICRF-Ext.1 catalogs (Ma & Feissel 1997). A total of 387 (out of 667 cataloged) ICRF-Ext.1 sources were observed during this survey, and new position estimates were made using dual–frequency VCS1 observations for 72 ICRF-Ext.1 sources with cataloged position errors greater than 0.5 mas rms. Fig. 1 shows the celestial distribution of the 667 ICRF-Ext.1 sources (top) and the 1332 VCS1 calibrators (bottom).

2.3. Calibration & Imaging

Amplitude and initial phase calibration of the survey was done using the National Radio Astronomy Observatory Astronomical Imaging Processing System (AIPS) software. Absolute amplitude calibration is achieved using internal noise calibration sources at the VLBA antennas. After fringe fitting, the amplitude and phase–calibrated data were exported to FITS format for imaging purposes. Automated imaging of the VCS1 sources to enable on–line access was carried out using the Caltech Difmap package. Starting with a point source model, iterations of Clean and self–calibration procedures were carried out until noise–like residuals were encountered, at which point a final naturally–weighted image was produced. A selection of the VCS1 candidate images is shown in Fig. 2. The typical image rms is
2–3 mJy, with a dynamic range of ∼30:1 or better. Of the total 1811 sources observed, approximately 1300 sources (70%) imaged automatically at 8.4 GHz. Additional sources were manually imaged. Calibrator candidates which failed to image generally had too little data, or were strongly resolved on a majority of VLBA baselines, indicating source sizes of greater than 10–20 mas. The images and $u$–$v$ radius plots for the VCS1 can be accessed online via a graphical search engine (NRAO 2001).

3. Astrometry

Astrometric processing of the VCS1 was performed at the NASA Goddard Space Flight Center using AIPS and the Calc/Solve software packages. Each epoch and each frequency band (2.3 and 8.4 GHz) was processed independently in AIPS. Electronic phase offsets were applied to the amplitude calibrated visibilities using either measured phase tone phases (epochs 4–10) or using phase offsets determined by fringe fitting a reference scan on a bright source (epochs 1–3). Phase and amplitude variations across the individual BBCs were estimated and corrected using a reference scan on a bright source. Individual baselines were then fringe fitted in AIPS to obtain residual single-band delays, multi-band (bandwidth synthesis) delays, phase delay rates, and fringe phases. These quantities were then combined with the correlator model to obtain total group delays, delay rates, and phases. Finally, the totals were shifted from geocentric quantities to the standard geodetic/astrometric reference–station baseline observables, and were written out in a form suitable for import into the Calc/Solve analysis package. Calc/Solve is a geodetic/astrometric VLBI analysis package, developed and maintained by the GSFC VLBI group and other partners for the international geodetic/astrometric community.

Calc computes theoretical delays and delay rates using astronomical and geophysical models following the IERS 1996 Conventions (McCarthy 1996), and is used by numerous correlators around the world, including the VLBA, Mark III, Mark IV, JIVE, DRAO and ATNF correlators. Solve performs a least squares fit between the observed and theoretical delays and delay rates, allowing numerous parameters to be adjusted. Ionosphere–corrected linear combinations of the observed 2.3 and 8.4 GHz band group delays were used in the analysis. Initially, Solve analyses were made of each epoch to resolve group delay ambiguities, to eliminate outliers (2–4% of observations), and to estimate preliminary VCS1 source positions. When all epochs were ready, a final Solve analysis was made of all VCS1 epochs simultaneously to estimate: (a) final source positions; (b) positions of all stations except one assumed as a reference; (c) rate of change of UT1; (d) nutation offsets; (e) troposphere path delays and station clock behavior; and (f) east–west and north–south troposphere gradients.
and their derivatives. Clocks and tropospheres were modeled by linear splines with 60 min intervals, with constraints on their rate of change imposed with reciprocal weights of 50 ps/hr and 5x10^{-14} s/s, respectively.

In total, 1811 radio sources were observed in the VCS1 campaign. Two known gravitational lenses, 0218+357 and 1830-211, as well as the radio source 0001-121 were excluded from the astrometric solution since the fringing process for different observations apparently chose peaks which corresponded to different source components. To align the VCS1 positions with the reference frame defined by ICRF-Ext.1, the positions of 315 ICRF-Ext.1 reference sources observed were fixed at their catalog values during the astrometric processing. These fixed sources have position error ellipses with semi-major axes of 1.0 mas or less (IERS 1999).

The positions of 1370 sources with three or more group delays at both 2.3 & 8.4 GHz were estimated from the VCS1 data. An additional 34 sources had fewer than two successful observations at 2.3 GHz but more than two good observations at 8.4 GHz. A supplementary solution using only 8.4 GHz group delays was made including these 34 sources. For 9 sources with fewer than ten dual–frequency delays but considerably more 8.4 GHz delays, the positions from the 8.4 GHz–only solution were also taken as being more reliable. Since VCS1 observations were made during the years of solar minimum, errors due to uncorrected ionospheric delays in the 8.4 GHz data were relatively small. The final VCS1 catalog contains positions of 1289 sources from the dual–frequency solutions, and 43 source positions derived from the 8.4 GHz–only solution.

In Table 2 the survey information for the first 10 sources in the VCS1 catalog is shown, including J2000 and IVS B1950 source names, J2000 positions and position errors, the correlation \( r \) between the position error estimates in right ascension and declination, the number of observations included (\( N_{\text{obs}} \)) and the solution origin (X/S – solution incorporates both 2.3 & 8.4 GHz group delays; X-only – solution incorporates only 8.4 GHz group delays; X+ – solution incorporates only 8.4 GHz group delays: 2.3 GHz group delays were available, but the number of 2.3 GHz group delays was significantly less than the number of 8.4 GHz group delays). The parameter \( r \) is a measure of the covariances of the right ascension and declination position estimates, with high values of \(|r| \geq 0.5\) generally indicating that the array geometry was not optimal during the observations of this source, leading to poor position estimation. There were 126 sources not detected at either band, or yielding only one measurement of group delay, and were therefore not used in the astrometric solution (these sources are listed in Table 3).

The VCS1 catalog, and a catalog containing improved positions for the 72 ICRF-Ext.1 sources solved for in the VCS1 dual–frequency astrometric analysis (Table 4), are available
online at http://www.nrao.edu/vlba/VCS1. Complete versions of Table 2 and Table 4 are also available in the electronic-only version of the journal.

3.1. Error Analysis

The observing methodology of the VCS1 was significantly different from that used by traditional geodetic/astrometric VLBI experiments. The major source of errors in geodetic/astrometric experiments is from fluctuations in the troposphere path delays, which are estimated from the observations themselves. In order to separate the troposphere from other parameters in the least-squares solution, the VCS1 observing schedules included observations of sources at both low and high elevation for each station every hour, and to cover the sky as uniformly as possible. Fig. 3 presents the sky coverage for a VLBI antenna (the North Liberty VLBA station) during a typical geodetic/astrometric experiment and during a VCS1 epoch. The VCS1 was observed in declinations strips, leading to significantly less uniform sky coverage. Therefore, one could expect that the VCS1 catalog positions may have some systematic errors due to poorer estimates of troposphere zenith path delay and horizontal troposphere gradients.

In order to investigate the presence of systematic errors of the VCS1 catalog a trial solution was made. The positions of all sources except the 57 reference sources were estimated, including 296 sources that were in both the VCS1 and ICRF-Ext.1 source lists. Vectors of the differences in positions between the trial solution and ICRF-Ext.1 for 272 sources with semi-major error axes less than 2 mas are shown in Fig. 4. No pattern is apparent, suggesting that systematic effects in the VCS1 astrometric analysis are small.

It has been found from analysis of different geodetic results (Ryan et al. 1993), such as baseline lengths, Earth orientation parameters, source positions, etc., that the formal errors of these estimated parameters should be scaled up by the factor of 1.5. Analysis of source positions have indicated that the actual errors generally have a noise floor (Ma et al. 1998). Therefore source positions errors in the ICRF catalog were inflated:

$$\sigma_r = \sqrt{(1.5 \cdot \sigma_f)^2 + a^2}$$

(1)

where $\sigma_r$ stands for the reported uncertainties, $\sigma_f$ stands for the formal errors and $a$ stands for the additive noise term.

For the VCS1 we have adopted a similar error model. We used the differences between the trial solution and the ICRF-Ext.1 catalog and obtained an additive noise term of 0.4 mas
for VCS1 source positions derived using ionosphere–free joint dual–frequency group delays, and a noise term of 1.0 mas when 8.4 GHz–only delays were used. This additive term makes $\chi^2$ per degree of freedom of the differences in source positions between the trial solution and ICRF-Ext.1 approximately unity. Reported uncertainties of source positions in the VCS1 catalog were inflated using equation (1) and these values of the additive noise terms.

A histogram of the distribution of the semi–major axes of the inflated error ellipses is presented in Fig. 5. In the VCS1 catalog 53% of sources catalog have errors less than 1 mas and only 8% of sources have errors greater than 10 mas. The median value of the VCS1 position error distribution is $\sim$0.9 mas while the median error of the ICRF-Ext.1 catalog is 0.5 mas. Typical geodetic/astrometric experiments focus on source samples with simple or known brightness distribution, and have much better sky coverage. The complex effects of undetermined and variable source structure on astrometric positions have been studied recently (Charlot 1990; Fey & Charlot 2000) and may be assessed for the VCS1 in the future using the results of automated imaging and follow–up observations. Multi–year phase-referencing observations using compact extragalactic reference sources taken from VCS1, ICRF-Ext.11 or other catalogs may be affected by source evolution and variability at the sub-mas level, and therefore careful monitoring of reference source structure or the use of multiple reference sources is required in high-precision astrometric applications.

4. Discussion

The mas–accurate positions for compact bright extragalactic radio sources presented in this survey will enable phase–referencing VLBI imaging of weak astronomical targets over large areas of the northern sky. The combined ICRF-Ext.1 and VCS1 sky density is sufficient to provide a calibrator within 3° of a random location north of $-30^\circ$ declination approximately 75% of the time, and within 5° in 96% of cases. Experiments requiring high astrometric accuracy, or in cases where no suitable cataloged VLBI calibrator can be found within a few degrees, may use weaker continuum sources close to the astronomical target if sufficient data recording bandwidth is available. These weaker continuum sources may be identified from lower–resolution surveys such as the NRAO VLA Sky Survey (Condon et al. 1998). Short and long–term source variability may vary the flux densities of the VCS1 sources by tens of percent in extreme cases, so weaker calibrators should be examined before use in critical applications.

Use of the VCS1 in scientific studies has already commenced. The parent survey to VCS1 – JVAS – has been extensively used to search for gravitationally–lensed systems (Patnaik et al. 1992; King et al. 1999). The existence or absence of gravitational–lens pairs on mas–
scales can be used to place limits on the cosmological abundance of supermassive compact objects in the mass range $\sim 10^6$ to $10^8 \, M_\odot$ (Wilkinson et al. 2001). Current studies based on samples of $\sim 300$ sources indicate that such objects cannot make up more than 1% of the closure density of the universe. This suggests that a population of supermassive black holes forming soon after the Big Bang does not contribute significantly to the dark matter content of the Universe.

Examination of the VCS1 images to identify compact–symmetric objects (CSOs) has been carried out (Peck & Taylor 2000), doubling the number of these objects available for follow–up observations, including the detection of neutral hydrogen absorption towards the radio components of some CSOs (Peck et al. 2000), which may indicate the presence of an obscuring atomic torus in the nucleus of these objects. CSOs have also been found to be remarkably stable flux calibrators (Fassnacht & Taylor 2001), so larger samples will prove valuable for VLA and VLBA flux monitoring experiments, such as measuring time delays in gravitationally lensed sources.

Additional surveys based on the VCS1 to identify sources suitable as geodetic and phase–referencing calibrators at high frequencies (22–90 GHz), and throughout the Galactic Plane, have recently commenced (Fomalont et al. 2001). Proper–motion studies of Galactic objects such as pulsars (Brisken et al. 2000) depend on dense grids of suitable low–frequency calibrators at low Galactic declinations, which VCS1 does not cover. The results of these efforts should further benefit the geodetic and astrometric communities.

At the present time, radio observations are the most accurate way to define the ICRS; however in future optical observations will likely play an important role. The Hipparcos stellar reference frame (Perryman et al. 1997) has been aligned with the ICRF to within 0.6 mas offset and 0.25 mas in rotation at epoch 1991.25 (Kovalevsky et al. 1997), and represents the optical realization of the ICRS. Over the next two decades, new optical interferometers and astrometry missions such as the NASA Space Interferometry Mission (Shao 1998), the US Naval Observatory Full–Sky Astrometric Mapping Explorer (Horner et al. 2000) and the European Space Agency’s Global Astrometric Interferometer for Astrophysics (Perryman et al. 2001) will achieve microarcsecond positional accuracies, requiring new definitions of the ICRS.

The authors thank the many NRAO, GSFC and USNO staff members who offered advice and assistance during this work. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.. AP is grateful to the New Mexico Space Grant Consortium for partial support during this project.

Table 1. VCS1 Observations

| Epoch | Date      | $\delta^a$ | $N_{\text{srcs}}^b$ | Mb/s | Notes |
|-------|-----------|------------|----------------------|------|-------|
| 1     | 08/12/94  | 50°–61°    | 216                  | 64   |       |
| 2     | 05/19/95  | 61°–79°    | 215                  | 64   |       |
| 3     | 07/15/95  | 00°–12°    | 216                  | 64   |       |
| 4     | 03/13/96  | 12°–24°    | 216                  | 64   | (d)   |
| 5     | 05/15/96  | 24°–34°    | 192                  | 128  |       |
| 6     | 06/07/96  | 34°–44°    | 192                  | 128  |       |
| 7     | 08/10/96  | 44°–51°    | 192                  | 128  | (d)   |
| 8     | 05/07/97  | 00°–14°    | 192                  | 128  |       |
| 9     | 07/02/97  | -14°–28°   | 191                  | 128  |       |
| 10    | 08/27/97c | -18°–30°   | 160                  | 128  |       |
|       |           |            | 78°–90°              | 32   | 128   |

*a* Declination range observed during each epoch.

*b* Number of VCS1 candidates sources observed per epoch. Approximately 10% of the sample was observed in multiple epochs to assess astrometric accuracy.

*c* Two declination ranges were observed during this epoch.

*d* Three epochs (01/02/96, 03/21/97 & 04/04/97) were abandoned due to poor weather at a majority of the VLBA sites.
### Table 2. VCS1 Catalog Sample

| J2000 name | IVS B1950 name | Right Ascension (J2000) | Declination (J2000) | $\sigma_{ra}$ mas | $\sigma_{dec}$ mas | $r$ | $N_{obs}$ | Code |
|------------|----------------|-------------------------|---------------------|-------------------|-------------------|-----|-----------|-------|
| J0000+4054 | 2358+406       | 00 00                   | 53.081551           | +40 54            | 01.79335          | 2.38| 2.11      | −0.16 | 22    | X/S   |
