Anterior Mesencephalic Cap Dysplasia: Novel Brain Stem Malformative Features Associated with Joubert Syndrome

F. Arrigoni, R. Romaniello, D. Peruzzo, A. De Luca, C. Parazzini, E. M. Valente, R. Borgatti, and F. Triulzi

ABSTRACT

SUMMARY: In Joubert syndrome, the “molar tooth” sign can be associated with several additional supra- and infratentorial malformations. Here we report on 3 subjects (2 siblings, 8–14 years of age) with Joubert syndrome, showing an abnormal thick bulging of the anterior profile of the mesencephalon causing a complete obliteration of the interpeduncular fossa. DTI revealed that the abnormal tissue consisted of an ectopic white matter tract with a laterolateral transverse orientation. Tractographic reconstructions support the hypothesis of impaired axonal guidance mechanisms responsible for the malformation. The 2 siblings were compound heterozygous for 2 missense variants in the TMEM67 gene, while no mutations in a panel of 120 ciliary genes were detected in the third patient. The name “anterior mesencephalic cap dysplasia,” referring to the peculiar aspect of the mesencephalon on sagittal MR imaging, is proposed for this new malformative feature.

ABBREVIATIONS: AMCD = anterior mesencephalic cap dysplasia; CST = corticospinal tract; IQ = Intelligence Quotient; JS = Joubert syndrome; SCP = superior cerebellar peduncle

The “molar tooth” sign is the distinctive imaging feature and a mandatory criterion for the diagnosis of Joubert syndrome (JS), a rare group of conditions characterized by a complex malformation of the midbrain-hindbrain. The molar tooth sign owes its name to the appearance of the pons and superior cerebellar peduncles (SCPs) on axial MR images, resembling a molar tooth. It is related to a moderate-to-severe vermian hypodysplasia, associated with a narrow pontine-mesencephalic junction and a thickened, elongated, horizontal SCP.

The typical clinical signs of JS (episodic hyperpnea, abnormal eye movements, developmental delay, and ataxia) may be associated with heterogeneous neurologic and non-neurologic symptoms and defects in other organs, including the kidneys, retina, liver, and skeleton, giving rise to an extremely large spectrum of phenotypes, from relatively mild to severe conditions.

JS is part of an expanding group of disorders called ciliopathies, caused by dysfunction of the primary cilium, a ubiquitous subcellular organelle that plays a key role in brain development and in many cellular functions. To date, >35 genes encoding for proteins of the primary cilium or its apparatus have been identified as causing JS; however, many patients remain undiagnosed; thus, further genetic heterogeneity is suggested. The variable degree of vermian hypodysplasia and the presence of associated supratentorial findings (hippocampal malrotation, callosal dysgenesis, migration disorders, hypothalamic hamartomas, cephaloceles, and ventriculomegaly) may further complicate the spectrum.

We report on 3 patients from 2 different families (2 brothers with genetically defined JS and 1 unrelated girl), presenting an additional complex malformation of the brain stem characterized by an abnormal thick bulging of the anterior profile of the mesencephalon. DTI revealed that the abnormal tissue consisted of an ectopic bundle of white matter with a laterolateral transverse orientation, likely resulting from impaired axonal guidance mechanisms during the early stages of brain development.
MATERIALS AND METHODS

Neuroimaging Data

Patients underwent MR imaging studies on either 3T (patients 1 and 2) or 1.5T (patient 3) scanners at 2 different institutions (Eugenio Medea Research Institute and “V. Buzzi” Children’s Hospital). Axial and coronal T2-weighted (thickness, 3 mm), axial and coronal FLAIR (thickness, 3 mm), and 3D T1-weighted echo-spoiled gradient-echo images (voxel size, 1 mm³) were acquired. Balanced steady-state free precession sequences were acquired at 3T to evaluate the cranial nerves. High-resolution DTI data (voxel size, 2 mm³; b-values, 0, 300, 1100 s/mm²; number of directions, 32) were available for the 2 patients examined at 3T, while the third patient had low-resolution DTI (voxel size, 3 mm³; b-values, 0, 1100 s/mm²; number of directions, 15).

DTI data were preprocessed with the DIFF_PREP module of TORTOISE (https://science.nichd.nih.gov/confluence/display/nihpd/TORTOISE) to remove motion and eddy current artifacts; then, correction of geometric EPI distortions was performed with DR-BUDDI using the dual-phase encoding acquisition. Fiber tractography was performed with TrackVis (http://www.trackvis.org/dtk/) in patients 1 and 2. We did not perform tractography in patient 3 because of the lower quality (ie, signal-to-noise ratio, resolution) of the data.

Clinical and Genetic Data

Neurologic, neuropsychological, and instrumental evaluations as well as genetic analysis were performed in all patients.

The local ethics committee approved the study. Written informed consent was obtained from all participating families.

RESULTS

Neuroimaging

The 3 patients showed a complex brain stem and cerebellar malformation, with normal findings in the supratentorial brain.

The main features of the common midbrain-hindbrain malformation were the following:

- A severe vermian hypodysplasia with a thickened, horizontal SCP determining a molar tooth shape of the superior brain stem on axial images (Fig 1)
- A flattening of the inferior olives and medullary pyramids (Fig 1)
A narrow isthmus, with a thin pontine-mesencephalic junction

A thickened tectum on the sagittal plane in patient 1

An abnormal bulging of the anterior profile of the mesencephalon on sagittal planes. On axial images, such bulging resulted in a complete obliteration of the interpeduncular fossa (white arrowheads). CSTs in the pons are thinned (black arrow) or not clearly recognizable, and transverse pontine fibers appear as a unique bundle displaced in the anterior part of the pons. In the medulla, CST and lemnisci are hypoplastic/atrophic and the olives are reduced in volume. The decussation of SCP (white arrow in the normal template) is absent in patients 1 and 2 and markedly thinned in patient 3 (white arrows in D). Red, green, and blue represent areas of transverse, anteroposterior, and caudocranial orientation of diffusivity and white matter, respectively.

Cranial nerves IX and X could be detected on balanced steady-state free precession sequences in patients 1 and 2. Patient 1 showed an agenesis of the left cranial nerve XII. The lower cranial nerves could not be assessed in patient 3.

Color-encoded DTI maps and tractography reconstructions revealed that the anterior mesencephalic bulging corresponded to a transversely orientated white matter tract in the interpeduncular cistern (Fig 2). On tractography, an apparent merging of corticospinal tracts (CSTs) with the abnormal mesencephalic bundle could be suspected.

On color-encoded DTI maps, CSTs could be regularly recognized only until the upper part of the pons (Fig 2). On tractography, pontine transverse fibers and middle cerebellar peduncles appeared as a thick unique bundle anteriorly displaced in the pons (Fig 3). The SCPs were thickened, while the inferior cerebellar peduncles were atrophic in patient 1. SCP decussation was absent in patients 1 and 2, and it was thinned in patient 3.
Genetic Findings
Clinical and genetic findings of the 2 siblings were reported in 2009 as part of a molecular genetic screening of the TMEM67 gene in patients with JS. They both were compound heterozygous for TMEM67 missense variants c. 1115C>H11022/p.(T372K) and c.2345A>G/p.(H782R), which were inherited from the healthy father and mother, respectively (Family COR32 in Brancati et al12). The third patient underwent next-generation sequencing-based analysis of a panel of 120 ciliopathy-related genes, which failed to identify any pathogenic variant.

Clinical Findings
Patient 1 is now a 14-year-old boy. He had impaired psychomotor development, with delayed motor acquisitions (able to walk independently at 6 years of age) and absence of expressive language. Currently, he uses sign language with good social interactions and skills. Diffuse hypotonia, dysmetria, oromotor dyspraxia, and gait ataxia with moderate intellectual disability (Performance IQ = 41) were evident at neurologic examination. A liver biopsy performed at 4 years of age demonstrated congenital hepatic fibrosis, hepatosplenomegaly, portal hypertension, and small esophageal varices. He also had an increase of transaminase and γ-glutamyltranspeptidase levels and thrombocytopenia secondary to hypersplenism.

Patient 2 is an 8-year-old boy. As with his older brother, he had delayed psychomotor development, walking unaided at 3 years of age and lacking any expressive language. Currently, he uses sign language with good social interactions and skills. Diffuse hypotonia, dysmetria, oromotor dyspraxia, and gait ataxia with moderate intellectual disability (Performance IQ = 41) were evident at neurologic examination. A liver biopsy performed at 4 years of age demonstrated congenital hepatic fibrosis, hepatosplenomegaly, portal hypertension, and small esophageal varices. He also had an increase of transaminase and γ-glutamyltranspeptidase levels and thrombocytopenia secondary to hypersplenism.

Patient 3 is an 11-year-old girl, the only child of consanguineous healthy parents (second-grade cousins). She presented early in life with mild motor delay, severe intellectual impairment, marked visual deficits, and nystagmus. On the latest neurologic examination, she presented with severe intellectual disability with poor expressive language and social skills, diffuse hypotonia, and clumsiness. She had severe visual impairment (1/50 bilaterally), nystagmus, and roving ocular movements. Fundus oculi showed nerve optic hypoplasia and small vessels, and electoretinography could not elicit any response. Abdominal sonography and audiometric evaluation findings were normal.

Clinical findings and instrumental evaluation are summarized in the On-line Table.

DISCUSSION
The presence of an anterior mesencephalic bulging due to an ectopic transverse white matter bundle represents a new malformative pattern of the midbrain for which we propose the name “anterior mesencephalic cap dysplasia” (AMCD). This definition is adopted and adapted from a previously described malformation of the brain stem, pontine tegmental cap dysplasia,14 which shares some common features with AMCD. In both cases, the
sagittal profile of the brain stem shows an abnormal "cap," which, in AMCD, is located anteriorly, at the mesencephalic level, while in pontine tegmental cap dysplasia, the cap is located posteriorly at the pontine level. Moreover, in both cases, on axial sections and DTI, the cap looks like a white matter ectopic bundle with a transverse laterolateral orientation.

Other diagnoses, like tumors, metastasis, or other proliferative disorders, could be easily excluded, considering their signal intensity and expansive/infiltrative features.

The presence of an interpeduncular mass in patients with JS was previously reported by Harting et al., who described 3 patients with a nodular structure within the interpeduncular fossa. Similar tissue can also be depicted, but not discussed, in several articles by Huppk et al.6 and Alorainy et al.17 Interpeduncular masses in JS probably represent a continuum, but we believe that according to their appearance on both morphologic sequences and DTI, a distinction between pedunculated and nonpedunculated structures can be maintained. Interpeduncular heterotopia is a nodular rounded structure, isointense to gray matter, with a peduncle that connects the mass to the brain stem, while AMCD is isointense to white matter, has no peduncle, and completely fills the interpeduncular fossa. Moreover, in AMCD, DTI confirmed the presence of an ectopic transverse white matter bundle anterior to the mesencephalon. Most interesting, according to tractographic reconstructions, the bundle appears to be in continuity with corticospinal tracts and may represent an ectopic decussation of the motor tracts. Careful interpretation of these findings is needed because the algorithm we used for tractography has limitations in resolving crossing or sharply angulated fibers,18 which are better handled by more sophisticated approaches, such as high angular resolution diffusion imaging (HARDI). Unfortunately, because of the characteristics of our protocol (low b-values, few diffusion directions), spherical deconvolution–based tractography did not improve the resolution of the tracts.

Anomalies in tract decussations (both CST and SCP) have been frequently described in neuropathologic reports of patients with JS.19-23 Moreover, the absence of CST decussation has been described in other conditions such as occipital encephalocele, Dandy-Walker malformation, Möbius syndrome, horizontal gaze palsy and progressive scoliosis, L1 syndrome, Kallmann syndrome, and trisomy 18,19-25 while there is no report of aberrant ectopic mesencephalic decussation.

More recently, Poretti et al9 described a convex protuberance of the ventral contour of the midbrain due to a nodular structure in 13 of 110 patients with JS, expanding the findings from Harting et al.19 No DTI data are shown, and the lesions are interpreted as gray matter heterotopia; however, the possibility of ectopic white matter projections is left open.

One single case has been previously reported of a fetus with JS at 22 weeks’ gestation, showing AMCD both at MR imaging and postmortem histology.26 As in our patients, in utero- and histology-based tractography confirmed the abnormal projection of the CSTs into the interpeduncular cistern. Both in the fetus and in our patients, the motor tracts were atrophic/barely recognizable in the pons and medulla.

The alternative hypothesis that the abnormal mesencephalic bundle represents an ectopic, aberrant white matter tract connecting either the cerebral or cerebellar hemispheres cannot be completely discarded, even if it is not supported by tractography. We also hypothesized that the tract could represent the decussation of the SCP displaced anteriorly, but in patient 3, SCP decussation was present (even if uncommon in JS, the persistence of SCP decussation is not exceptional because it was already reported in neuropathologic studies21); in the 2 siblings, we could not identify a direct connection between SCP and the bundle. Pathologic confirmation is needed to fully understand the course of the abnormal tract and its origin.

Mirror movements, often associated with abnormal pyramidal decussation, resulting in bilateral CST projections to the spinal cord were not detected in our patients.21 Functional MR imaging during motor tasks would be of help to verify the decussation of the CST, but it could not be performed due to the insufficient cooperation of patients.

The 2 siblings had mutations in the TMEM67 gene, a ciliary gene that is expressed in the brain midline, hindbrain, retina, kidney, liver, and developing sphenoid bone and plays a fundamental role in centriole migration to the apical membrane and formation of the primary cilium.29 Most interesting, TMEM67 represents the gene for which the strongest gene-phenotype correlates have been drawn.29-31 In fact, nearly all patient with JS and the TMEM67 mutation have congenital liver fibrosis, variably associated with optic nerve or chorioretinal coloboma, retinal dystrophy, and renal involvement (COACH syndrome).32-34

Mounting evidence suggests a central role for the primary cilium in modulating neurogenesis, cell polarity, axonal guidance, and possibly adult neuronal functions.5,6 The lack of decussation of the CST and SCP reported in neuropathologic and DTI tractography studies of patients with JS suggested that defective primary cilium could also impair the process of axonal guidance, and the presence of an aberrant/ectopic white matter tract in patients with a proved ciliopathy can further support this theory.

Aberrant or ectopic white matter tracts have been detected in a wide spectrum of malformations involving the brain stem and corpus callosum,24-40 as a result of defects in axonal guidance or other mechanisms. The advent of high-resolution MR imaging and DTI along with the advances in genetic technologies helped to define and expand human disorders of axonal guidance and will probably contribute to the discovery of many additional similar conditions in the future.

CONCLUSIONS

Through high-resolution MR imaging, DTI, and tractography, we demonstrated that nonpedunculated interpeduncular tissue in JS may represent an ectopic transverse white matter tract located in the mesencephalon, for which the name "AMCD" is proposed.

ACKNOWLEDGMENTS

We are grateful to patients and their family for cooperation in this study.
