Diffusion-Based Coarse Graining in Hybrid Continuum–Discrete Solvers: Theoretical Formulation and A Priori Tests

Rui Sun, Heng Xiao

Department of Aerospace and Ocean Engineering, Virginia Tech, Blacksburg, VA 24060, United States

Abstract

Coarse graining is an important ingredient in many multi-scale continuum-discrete solvers such as CFD–DEM (computational fluid dynamics–discrete element method) solvers for dense particle-laden flows. Although CFD–DEM solvers have become a mature technique that is widely used in multiphase flow research and industrial flow simulations, a flexible and easy-to-implement coarse graining algorithm that can work with CFD solvers of arbitrary meshes is still lacking. In this work, we proposed a new coarse graining algorithm for continuum–discrete solvers for dense particle-laden flows based on solving a transient diffusion equation. Via theoretical analysis we demonstrated that the proposed method is equivalent to the statistical kernel method with a Gaussian kernel, but the current method is much more straightforward to implement in CFD–DEM solvers. A priori numerical tests were performed to obtain the solid volume fraction fields based on given particle distributions, the results obtained by using the proposed algorithm were compared with those from other coarse graining methods in the literature (e.g., the particle centroid method, the divided particle volume method, and the two-grid formulation). The numerical tests demonstrated that the proposed coarse graining procedure based on solving diffusion equations is theoretically sound, easy to implement and parallelize in general CFD solvers, and has improved mesh-convergence characteristics compared with existing coarse graining methods. The diffusion-based coarse
graining method has been implemented into a CFD–DEM solver, the results of which will be presented in a separate work.

**Keywords:** CFD–DEM, Coarse Graining, Multi-scale Modeling

1. Introduction

1.1. Coarse Graining in Continuum-Discrete Modeling

In computational mechanics for solids and fluids, continuum methods such as those based on finite-difference, finite-volume, or finite-element discretizations of particle differential equations (e.g., Navier–Stokes or elasticity equations) are usually used to investigate macroscopic response of systems, e.g., structural deformations or fluid flows in the system of concern [1, 2, 3]. On the other hand, discrete methods such as molecular dynamics and direct simulation Monte Carlo methods are used to simulate microscopic properties of systems at length- and time-scales that are much smaller than those studies by using continuum methods [4, 5]. Continuum and discrete methods are complementary to each other, not only in terms of the length- and time-scales they cover, but also because they are used for different purposes. For example, in fracture mechanics, while continuum methods are better suited for simulating the fracture propagation in a solid or a structure, the constitutive model for fracture initiation and growth, which are must be given as input to the continuum method, must often be obtained by using discrete methods such as molecular dynamics simulation [6]; in fluid dynamics, continuum methods are used to study the overall flow behavior such as pressure distribution, flow rate, separation, and transition from laminar to turbulent flows in the system, while discrete methods are used to investigate the rheology of complex fluids [7, 8], the models of which are used in continuum methods.

Traditionally, continuum and discrete methods have been developed in separate communities without significant interactions. This is partly a reflection of the scale separation in classical continuum mechanics; that is, the scales of the representative volume element (RVE) are many orders of magnitude larger than those of the individual molecules or atoms therein. As a consequence, the phenomena of
interests in the macroscopic scales and those in the microscopic scales are dramatically different. However, the past few decades have seen a surge of interests in the development of methods aiming for bridging the continuum and the microscopic scales. These efforts originate from several communities with a diverse physical settings ranging from fracture mechanics \[6, 9\] and complex fluids \[8\] to materials sciences \[e.g., 10, 11, 12, 13, 14\]. In spite of these efforts, many theoretical and practical challenges exist in these multi-scale models. A particular difficulty that is common among most continuum–discrete solvers is the coupling between the continuum solver and the discrete solver with guaranteed conservation of relevant quantities. This is due to the fact that the conservation equations on the two scales are formulated for quantities of vastly different natures, and thus the bridging between the microscopic and macroscopic quantities are critical yet extremely difficult to achieve \[9, 10\]. A thorough review of challenges in the continuum–discrete coupling and the coarse graining in various physical contexts is beyond the scope of the present work. In this work we highlight the difficulties of coarse graining in the context of continuum–discrete solvers for dense particle-laden multiphase flows. Subsequently, a strategy that is theoretically meritorious and convenient for numerical implementations is proposed. However, since the difficulties associated with coarse graining are common among many other continuum–discrete methods, it is expected that the strategy developed in this work shall be useful for those methods as well.

1.2. Coarse Graining in CFD–DEM Solvers

Dense particle-laden flows are encountered in a wide range of industrial applications and natural processes including fluidized-bed reactors in chemical engineering \[15, 16\], pneumatic conveyors in the mineral processing industries \[17\], and sediment transport processes in riverine and coastal flows \[18, 19\]. A class of continuum–discrete methods have been proposed and developed in the past two decades, where the fluid (the carrier phase) is modeled with a continuum approach in the Eulerian framework, while the particles (the dispersed phase) are tracked individually in the Lagrangian framework accounting for the inter-particle colli-
sions and fluid–particle interactions. Compared with other alternatives such as the two-fluid model and direct numerical simulations [20, 21, 22, 23], the continuum–discrete approach is able to resolve much of the particle flow physics without requiring excessive computational costs. As such, it has received much attention in multiphase flow research communities and gained increasing popularity in industrial applications as well.

Proposed in the 1990s by Tsuji [24], the CFD–DEM (Computational Fluid Dynamics–Discrete Element Method) approach is the earliest developed continuum–discrete method for dense particle-laden flows. Other variants such as LES (Large Eddy Simulation)–DEM and SPH (Smooth Particle Hydrodynamics)–DEM have been developed recently [e.g., 25, 26, 27]. However, since the coarse graining procedure is common among this type of the continuum-discrete methods, in this work we describe the coarse graining method with CFD–DEM applications in mind. The proposed method is, however, applicable to other similar methods as well.

In CFD–DEM, the fluid is described by the volume-averaged Navier–Stokes equations [28]. The effects of the particle-to-fluid interactions are accounted for in the fluid continuity and momentum equations mainly through the presence of the following three terms: solid volume fraction $\varepsilon$, solid phase velocities $\mathbf{U}_s$, fluid–particle forces $\mathbf{F}_{fp}$ (primarily consisting of drag force $\mathbf{F}_d$ and buoyancy). These are field quantities based on the CFD mesh, and are obtained from the locations, the sizes, and the velocities of each individual particles as well as the fluid forces acting on them. The process of obtaining macroscopic quantities from particle-scale quantities is referred to as coarse graining in this work. It has also been called aggregation or averaging in the literature [29, 30]. This seemingly simple operation involves several challenges when performed in practical CFD–DEM solvers. First, theoretically the procedure is not unique [30], but the coarse grained fields can have profound influences on the CFD–DEM simulation results. Second, there are several constraints on the procedure, e.g., it must conserve the relevant physical quantities such as particle mass and momentum, both for the interior particles and for those near the domain boundaries (e.g., walls). Satisfying
these constraints simultaneously is challenging. Moreover, since industrial CFD simulations often involve complex geometries and necessitate using meshes of poor quality, the procedure should be able to accommodate these meshes without negatively impacting the CFD–DEM simulation results. Finally, it should be easy to implement and amiable to parallelization, a technology that is ubiquitously used in modern CFD codes. Numerous coarse graining techniques have been proposed and used in the literature [29, 30, 31, 32]. To the authors’ knowledge, however, a method satisfying all the criteria above is still lacking. The objective of this work is to develop a coarse graining strategy that is theoretically sound, easy to implement in industrial CFD solvers, and capable of handling generic meshes used in these CFD solvers. Due to space considerations, the current paper focuses primarily on the theoretical analysis and a priori evaluations of the proposed method without actually testing it in a CFD–DEM solver. Its implementation in CFD–DEM solvers and the evaluation of the performances are deferred to a separate publication [33].

The rest of the paper is organized as follows. In Section 2 the desirable features of coarse graining methods are discussed in detail, and existing algorithms in the literature are reviewed, compared, and evaluated against the properties in this list. Section 3 presents the proposed coarse graining algorithm, demonstrates its theoretical equivalence to the statistical kernel method, and examines its characteristics based on the theoretical analysis. In Section 4, a priori coarse graining tests are conducted to examine the performance of the proposed method and to compare with the results obtained with other coarse graining methods. Implementation details and computational costs considerations are discussed in Section 5. The paper is concluded in Section 6.

2. Review of Existing Coarse Graining Methods

Some of the commonly used and recently developed coarse graining methods in the CFD–DEM literature include the particle centroid method (PCM), the divided particle volume method (DPVM), the statistical kernel method, and the recently proposed two-grid formulation. These methods will be critically reviewed
below with their advantages and shortcomings examined. The discussion here is constrained to particle-resolving simulations where particle–fluid interfaces are not resolved. The continuum–discrete solvers where particle interfaces are explicitly resolved, e.g., with immersed boundary method [21] or Lattice-Boltzmann method [34, 35, 36], are beyond the scope of the present work, since the coarse graining algorithms discussed in this paper are not directly applicable to those methods. The methods where particles are represented as porous bodies are omitted from the discussion here as well.

2.1. Desirable Properties of Coarse Graining Procedure in CFD–DEM Solvers

In the context of implementation in CFD–DEM solvers for particle-laden flows, we first outline below a few desirable properties a coarse graining method should have. This “wish list” will serve as the basis for the evaluation and comparison of the existing and proposed coarse graining methods.

Based on physical reasoning and from our experiences in conducting CFD–DEM simulations, a coarse graining procedure should ideally:

1. conserve relevant physical quantities.

For example, when calculating solid volume fraction field \( \varepsilon_s \), the particle phase mass should be conserved, i.e., the total mass computed from the coarse grained continuum field should be the same as the total particle mass in the discrete phase. The conservation requirement can be written as follows:

\[
\rho_s \sum_{k=1}^{N_c} \varepsilon_{s,k} V_{c,k} = \sum_{i=1}^{N_p} \rho_s V_{p,i},
\]

where the density \( \rho_s \) is assumed to be constant for all particles; \( N_c \) is the number of cells in the CFD mesh or the mesh used for coarse graining, which are sometimes the same; \( N_p \) is the number of particles in the system; \( \varepsilon_{s,k} \) and \( V_{c,k} \) are the solid volume fraction and the volume, respectively, of cell \( k \). Similar conservation requirements must be met for the momentum of the particles and that of the entire fluid–particle system as well. That is, when calculating solid phase velocity, the total momentum of the particles should
be conserved; to conserve momentum in the fluid–particle system the total particle forces on the fluid should have the same magnitude as the sum of the forces on all particles but with opposite direction.

2. be able to handle particles both in the interior cells and the cells near boundaries without producing artifacts, including physical boundaries and processor boundaries in parallel computing.

3. be able to achieve relatively mesh-independent results;

The mesh independence or mesh convergence basically requires that the mesh used in computational simulations should be fine enough so that further mesh refinements do not lead to changes in the results. While this is a basic requirement for almost any mesh-based discretization methods for partial differential equations (e.g., finite difference, finite element), mesh convergences are not trivial to achieve in CFD–DEM simulations. The reason is that in most existing coarse graining methods the mesh is not only used for the discretization of the CFD conservation equations, but also determines the coarse graining bandwidth, an important computational parameter. Similar difficulties with mesh-convergence are well-known for LES with implicit filtering, where the mesh cell size determines the filter size, which is a computational parameter [37].

4. be convenient for implementation in parallel, three-dimensional CFD solvers based on unstructured meshes with arbitrary cell shapes;

5. be able to produce smooth coarse grained fields even with the presence of a few large particles in relatively small cells.

In a simulation using a uniform CFD mesh and a particle system with a wide particle diameter distribution (e.g., well-sorted natural sand), the cell size to particle diameter ratio can be small at the vicinity of the large particles. Moreover, in practical CFD–DEM simulations small cells are often required in certain regions to resolve the flow features therein (e.g., shear layers or jets with strong velocity gradients [38]), particularly when high fidelity flow solvers such as those based on LES are used for the fluid phase. It is important for the coarse graining algorithms to be able to handle these
situations, since abnormally large values or gradients in the solid volume fraction, velocity, or fluid–particle interaction forces, even in only a few cells, can destabilize the entire simulation or cause unphysical artifacts.

Items 1 and 2 above are essential, without which the coarse graining procedure would cause the CFD–DEM solvers to produce unphysical results. Items 3–5 are highly desirable, without which the coarse graining procedure would impose significant restrictions on the CFD–DEM solvers and limit their applications in practical simulations.

2.2. Particle Centroid Method

In the particle centroid method, only the particles whose centroids fall within a cell are counted for calculating the coarse grained continuum quantities (e.g., solid volume fraction \( \varepsilon_s \), solid phase velocity \( \mathbf{U}_s \), drag force \( \mathbf{F}_d \)) for this cell. For simplicity we use here the calculation of \( \varepsilon_s \) to illustrate the difference among the coarse graining methods. The coarse graining of other variables such as solid phase velocity and drag forces can be performed in the same way. In the configuration illustrated in Fig. 1(a), with the PCM all the particles, P1, P2, and P3, are counted towards the solid volume fraction of cell 1. All other cells have zero solid volume fraction. It can be seen that when the particle centroid is located near cell boundaries (e.g., particle P2 in Fig. 1(a)), the error can be up to 50% [32]. If a cell contains several such particles and if these particles are large compared to the host cell, unphysically large values can occur for this cell, leading to a non-smooth solid particle volume field with large gradients. Such non-smoothness in the coarse grained fields often causes spurious features in CFD–DEM simulations. However, except for this drawback, this seemingly unsophisticated method works very well otherwise, particularly when the cells are large compared to particle diameters. Moreover, if done properly the PCM can be made to satisfy the conservation requirement specified above in a straightforward manner. Finally, its implementation is straightforward even in parallel CFD solvers with unstructured meshes. As such, the PCM is one of the most widely used coarse graining procedures in the literature [e.g., 39].
2.3. Divided Particle Volume Method

The divided particle volume method, also referred to as analytical method [32], was proposed by Wu et al. [31] to address the above-mentioned drawback of the particle centroid method caused by particles intersecting multiple cells. Instead of counting the entire particle volume to the cell containing its centroid, in DPVM a particle’s volume is divided among all cells it overlaps, with each cell receiving the actual volume inside it. This is illustrated in Fig. 1(b). The volume of particle P1 is divided between cells 1 and 2, with cell 1 sharing the shaded portion. The volume of particle P2 is similarly shared between cells 4 and 2. It has been demonstrated [32] that the dividing particle volume method gives much smoother coarse grained solid volume fraction field than the PCM does, and the corresponding CFD–DEM results were significantly improved as well. However, in unstructured CFD meshes where cells can be of arbitrary shape, dividing particle volumes among intersecting cells requires accounting for many scenarios, which is tedious to implement. Even for a three-dimensional Cartesian mesh with cubic cells (the simplest mesh one can hope for in practical CFD simulations), there are seven particle–cell intersecting scenarios to account for. The readers are referred to Table 1 in ref. [32] to appreciate the complexity of DVPM. While Wu et al. [31] implemented a DPVM for typical cells shapes (e.g., tetrahedra and wedge) based on a commercial finite volume CFD solver, we are not aware of any implementations that are general enough to accounts for all cell shapes. Moreover, if the mesh contains small cells with sizes comparable to or smaller than some large particles, the analytical method would still lead to unphysically large solid volume fractions in these small cells.

2.4. Two-Grid Formulation

Another recent attempt to address the deficiency of the PCM in the cases of small cell-size to particle diameter ratios was made by Deb and Tafti [40]. Their idea was to use a separate mesh for the coarse graining and another mesh for the CFD simulation. The two meshes are constructed independently. Specifically, the coarse graining mesh is chosen based on particle diameters to ensure that the cell
Figure 1: Schematic of the four coarse graining methods: (a) the particle centroid method (PCM), (b) the divided particle volume method (DPVM), (c) the two-grid formulation, and (d) the statistical kernel function method. In (a), (b), and (d), the shades indicate the coarse grained solid volume fraction fields $\varepsilon_s$. In (a) the PCM, $\varepsilon_s$ is nonzero only for cell 2, which contains the centroids of all particles; in (b) the DPVM, all cells 1, 2, and 4, which overlap with a portion of at least one particle have nonzero $\varepsilon_s$; in (c) two grid formulation, two separate meshes are used for coarse graining (thick lines) and fluid simulation (thin lines); in (d) the statistical kernel method, theoretically all cells can have non-zero $\varepsilon_s$. 
sizes \( \Delta x \) are larger than particle diameters \( d_p \) (they used \( \Delta x = 3d_p \)), and the CFD mesh is chosen according to the flow resolution requirements. They used structured Cartesian meshes similar to the one shown in Fig. 11(a). As can be seen from Fig. 11(a), each cell in the coarse graining mesh (displayed in thicker lines), contains exactly \( 3 \times 3 \) fluid mesh cells (thin lines). This configuration with aligned cell boundaries simplifies the implementation dramatically, and it is relatively easy to achieve on a structured Cartesian mesh. In parallel CFD solvers with unstructured meshes, however, the implementation of the two-grid formulation is not straightforward. For these solvers, using two meshes with arbitrarily aligned cells would increase the complexity of the implementation and necessitate non-trivial interpolations between the two meshes. Alternatively, to ensure alignment of coarse graining mesh cells and CFD cells, the latter of which may be of arbitrary shape, one can construct a coarsened mesh based on a fine CFD mesh via agglomeration. In fact, mesh agglomeration is common in geometric multi-grid methods for linear equation systems [41], which is used in many general-purpose unstructured CFD solvers. Such a fine CFD mesh and the corresponding agglomerated coarse mesh is shown schematically in Fig. 1(c). However, agglomeration across processor boundaries in parallel computing is not easy to implement, and in multi-grid methods for linear system the agglomeration is generally not performed across cells on different processors [41]. Restricting agglomeration within the mesh on the same processor would impose serious limitations on the effectiveness of the two-grid formulation. To our knowledge such a two-grid formulation in a parallel CFD solver with unstructured mesh does not yet exist in the literature.

2.5. Statistical Kernel Method

Yet another class of coarse graining methods are based on statistical kernel functions, which will receive a more thorough discussion here since it is the foundation for the method proposed in this work.

2.5.1. Formulation for Particles in Interior Cells

In the statistical kernel method the volume of each particle is distributed to the entire domain according to a weight function called kernel function \( h(x) \). This
is illustrated in Fig. 1(d). The solid volume fraction at location $x$ consists of the superposition of the distributed volumes from all particles, i.e.,

$$\varepsilon(x) = \sum_{i=1}^{N_p} V_{p,i} h_i$$  \hspace{1cm} (2)

where $h_i = h(x - x_i)$ is the weight function for particle $i$. Possible choices of kernel functions include top hat function (with which the method essentially degenerates to PCM), Gaussian distribution function [29, 42], and Johnson’s $S_B$ distribution function [43, 30]. The Gaussian kernel function is of particular interests to the current study due to its analytical tractability. In three-dimensional space the Gaussian kernel function for particle $i$ is:

$$h_i = h(x - x_i) = \frac{1}{(b^2 \pi)^{3/2}} \exp \left[ -\frac{(x - x_i)T(x - x_i)}{b^2} \right] \hspace{1cm} (3)$$

where superscript $T$ indicates vector transpose; $b$ is the bandwidth of the Gaussian kernel, indicating the size of the region influenced by the particle (i.e., the cells whose solid volume fractions “receives” contribution from the particle); $x_i$ is the location of particle $i$. Note that for the coarse graining procedure to have the conservation property, the kernel function $h$ must satisfy the normalization condition, i.e.,

$$\int_{\mathbb{R}^3} h(x) \, dx = 1, \hspace{1cm} (4)$$

where $\mathbb{R}^3$ is the entire three-dimensional spatial domain. The Gaussian distribution function as in Eq. (3) is known to satisfy this condition. As pointed out by Zhu and Yu [30], in addition to the normalization requirement, a kernel function should have local, finite, and compact support, i.e., it is nonzero only at a finite region in the neighborhood of the peak. Although the Gaussian distribution function has an infinite support theoretically, over 99% of the weight distribution is contained within a sphere of radius $3b$, which can be considered as the effective support of the kernel. In numerical codes such as CFD–DEM solvers, the Gaussian kernel can be considered as a function with effective local support [44].

Statistical kernel based averaging is a theoretically elegant method for coarse graining from the discrete particle phase to a continuum descriptions of granular
flows \cite{30,45}. It resembles the technique used to bridge molecular dynamics in micro-scales and continuum mechanics in macro-scales. Zhu and Yu \cite{30} demonstrated that with the statistical averaging one can derive from the equations at the DEM level to a continuum level balance equation for the granular flow. Posterior tests showed good performance of the scheme by using the Johnson’s $S_B$ distribution function. However, its implementation in CFD–DEM solvers is not trivial since the volume of a particle are distributed not only to local cells, but also to nonlocal cells that may be located many layers of cells away from the particle location (e.g., those inside the dashed circle in Fig. 2), some of which may be even located on another processor. Searching for these cells in unstructured meshes is challenging, since the stored connectivity information in unstructured meshes normally only allows each cell’s immediate neighbors to be found. To find information of cells further away, one needs to find the immediate neighbors, and then find the neighbors of all immediate neighbors, and repeat this process recursively until all the cells “receiving” the volume of the particle are identified \cite{29}. This process needs to be repeated for the volume distribution of each particle. The recursive nature of these search operations makes them time-consuming, although it is performed only once in the beginning of the simulation if the mesh does not move during the simulation. More importantly, the need for particles to communicate to non-local cells makes it challenging for implementations in parallel solvers based on MPI (Message Passing Interface) \cite{46}, a technology that is utilized by most modern CFD solvers \cite{e.g.,47}.

\subsection*{2.5.2. Treatment of Physical Boundaries (Walls)}

The scheme in Eq. (3) is applicable for particles in the interior cells. That is, particles that are “far away” from wall boundaries, i.e., those whose influence regions do not insect with boundaries. This scenario is depicted in Fig. 3. Here we are only concerned with physical boundaries of the system, i.e., mostly wall boundaries, although symmetry plane boundaries can be treated in the same way. Computational boundaries such as inter-processor boundaries are not considered since they should not pose theoretical difficulties.
The non-local nature of the method is illustrated by the fact that the cells whose solid volume fractions are influenced by the particle (indicated as those inside the dashed circle) can include and non-local cells far away from the particle, possibly on different processor (processor 1) than the one on which the particle is located (processor 0).

For particles that are located near wall boundaries, Zhu and Yu [30] modified the kernel function $h_i$ in Eq. (3) to the following:

$$\tilde{h}_i = h(x - x_i) + h(x - x'_i), \quad (5)$$

where $x'_i$ is the location of the image of the particle located at $x_i$ with respect to the physical boundary, shown in Fig. 4(b). They showed that the modified kernel function $\tilde{h}_i$ also satisfies the normalization condition in Eq. (4). This modification has a straightforward physical interpretation as illustrated in Fig. 4. When a particle is close to the physical boundary, if the kernel function $h_i = h(x - x_i)$ as in Eq. (3) were used, part of the volume (indicated as wavy pattern in Figs. 4(a) and 4(b)) would be distributed to regions outside the physical domain. In view of the normalization condition Eq. (4), this would violate the conservation principle, since the integration domain does not cover the entire space. It can be seen that the kernel function $h(x - x'_i)$ adds the same amount that is distributed outside the physical domain by the kernel function $h_i$ to inside the domain (the shaded region in Fig. 4(b)), exactly compensating for the lost part and thus restoring the conservation. Although other methods such as renormalization can also restore
the conservation \cite{29,18}, the image kernel method is clearly more physical and elegant.

![Figure 3: Distribution of particle volume to cells in the statistical kernel method for interior particles away from boundaries. The shade shows the distributed volume of the particle with the kernel function $h(x-x_i)$. The solid volume fraction of the cells outside the circle (regions that are not shaded) are not influenced by this particle, and thus the presence of the physical boundary does not influence its volume distribution.](image)

Although not explicitly treated in Zhu and Yu \cite{30}, the method of images above as in Eq. 5 can be extended to treat more complex boundaries. The most straightforward extension is to account for the present of two boundaries, e.g., a particle located at the corner in a two-dimensional domain, as illustrated in Fig. 5(a). In this case the modified kernel function consists of four terms, with one associated with the physical particle and three with image particles. The kernel function for particle $i$ is thus

$$\tilde{h}_i = \sum_{n=0}^{n=3} h_i^{(n)},$$

(6)

where $n$ is the index of the terms in the series, with $h^{(0)}$ being the physical kernel and other being image kernels. For a three-dimensional corner, the total number of terms in the kernel function would be eight, with one physical kernel and seven image kernels. Graphical illustration for this case is omitted here. For all the three cases above, the modified kernel functions satisfy the normalization requirement exactly regardless of the kernel bandwidths and the distances between the particle
Figure 4: Statistical kernel based coarse graining for a particle volume near a physical boundary. The kernel function $h(x - x_i)$ for the physical particle located at $x_i$ is shown on the physical domain (left to the boundary); the kernel function $h(x - x'_i)$ for the image particle located at $x'_i$ is shown on the image domain (right to the boundary). The kernel function $\tilde{h}_i = h(x - x_i) + h(x - x'_i)$ based on the superposition of the two functions above are shown on the physical domain in the top panel with shade and in the bottom panel with solid line.
and the boundaries, thanks to the orthogonality of the boundaries in the two- and three-dimensional cases. For a particle located near multiple boundaries that are non-orthogonal, a scenario that can be encountered in complex geometries, the exact expression for the modified kernel function consists of an infinite series:

\[ \tilde{h}_i = \sum_{n=0}^{\infty} h_i^{(n)}, \]  

(7)

where \( n \) is the index of the individual kernels, with \( h_i^{(0)} \) centered at the physical particle and \( h_i^{(n)} \) (where \( n = 1, 2, \ldots, \infty \)) centered at the image particles. This is illustrated in Fig. 5(b), showing the locations of the physical kernel and the first seven image kernels. Since the kernels have finite support (bandwidth), the image kernels in the series located far away outside the computational domain can be safely truncated without impairing the accuracy. In spite of this, it can be seen that the complexity of the kernel function associated with a near-boundary particle, particularly for one that is located near a corner with several non-orthogonal boundaries, is significant. Indeed, coarse graining strategy near boundaries is an important and difficult subject that has been the focus of several recent publications [48, 49]. On the other hand, we point out that, at least in the context of CFD–DEM simulations, this difficulty related to boundaries is unique to sophisticated coarse graining schemes such as the statistical kernel method, as the presence of boundaries hardly poses any difficulties for the relatively simple coarse graining schemes such as PCM and DPVM, although in some cases they can make it difficult to construct a coarse graining mesh in the two-grid formulation.

2.6. Overview of Proposed Diffusion-Based Coarse Graining Method

In this work, we propose a diffusion-based coarse graining method consisting of the following two steps (using again the solid volume fraction \( \varepsilon_s \) as example):

1. Perform averaging based on the particle centroid method to obtain the coarse grained field, denote the field as \( \varepsilon_0 \); and

2. Integrate a transient, homogeneous diffusion equation for a period of pseudo-time \( T \), using the field \( \varepsilon_0 \) as initial condition and no-flux conditions on all physical boundaries. The obtained field \( \varepsilon_s(T) \) is the coarse grained field.
Figure 5: Physical and image kernels for a particle located near multiple boundaries showing the scenarios of (a) orthogonal and (b) non-orthogonal boundaries, the later of which involve the summation an infinite series of kernels and only the first eight terms are shown here.
In the rest of the paper we will show that this scheme is theoretically equivalent to the statistical coarse graining method presented in Section 2.5 and the pseudo time-span $T$ is determined according to the bandwidth of the kernel function. The equivalence is valid even with the presence of boundaries, and no special treatment for boundaries is needed in the proposed method. We will further demonstrate the following merits of the proposed method:

1. Straightforward implementation in almost any CFD code by solving a few additional diffusion equations;
2. Ability to obtain smooth coarse grained fields even with cell sizes comparable or slightly smaller than particle diameters; and
3. Relatively mesh-independent; and
4. No additional difficulties in implementations in parallel CFD solver using unstructured mesh with arbitrary cell shapes.

The advantages and limitations of the coarse graining methods reviewed above are summarized in Table 1.

3. Diffusion-Based Coarse Graining Algorithm

3.1. Summary and Heuristic Reasoning

In the particle centroid method, the coarse graining from Lagrangian particle data to Eulerian mesh-based field (e.g., solid volume fraction) is done as follows. We loop through all cells, and for each cell we sum up all the particles volume to their host cells (defined as the cell within which the particle centroid is located) to obtain the total particle volume in each cell. The solid volume fraction of each cell $k$ is then obtained by dividing the total particle volume in the cell by the total volume of the cell $V_{c,k}$. That is,

$$\varepsilon_{s,k} = \frac{\sum_{i=1}^{n_{p,k}} V_{p,i}}{V_{c,k}},$$

where $n_{p,k}$ is the number of particles in cell $k$, which implies that $\sum_{k=1}^{N_c} n_{p,k} = N_p$. Multiplying both sides of Eq. (8) by $V_{c,k}$ and taking summation over all cells, the
Table 1: Comparison of advantages and disadvantages of coarse graining methods in the literature and the currently proposed method.

| coarse-graining methods | implementation in generic CFD solvers\(^{(a)}\) | smoothness for small \(\Delta x/d_p\)\(^{(b)}\) | mesh convergence | boundary treatment |

- (a) a parallel CFD solver based on unstructured mesh with cells of arbitrary shapes and connectivity
- (b) \(\Delta x/d_p\) indicates cell-size to particle diameter ratio, where \(\Delta x\) is mesh cell size, and \(d_p\) is particle diameter
- (c) if \(\Delta x/d_p\) is approximately 2 or larger
- (d) if the kernel bandwidth (or coarse graining mesh size) is chosen independent of the CFD mesh cell size
conservation requirements in Eq. (1) can be recovered. Therefore, the PCM-based coarse graining is conservative by construction.

As mentioned in Section 2.2, the coarse grained fields so obtained may have large gradients. The cells with large solid volume fraction are shown schematically as three box-car functions in Fig. 6. The ticks indicate cell centers. To address this issue of non-smoothness, a straightforward idea is to smooth this field via diffusion, i.e., by solving a diffusion with non-smooth fields as initial conditions. The diffusion equation essentially redistributes particle volumes within the field while automatically conserving total solid volume in the domain during the diffusion. To ensure conservation of mass, no-flux (i.e., zero gradient) conditions should be specified at all physical boundaries except for periodic boundaries, where periodic conditions should be used instead. The smoothened field so obtained is shown in Fig. 6 as thick dashed line.

3.2. Equivalence to Statistical Kernel Method

3.2.1. Particles in Interior Cells

Consider the diffusion equation for \( \varepsilon(x, \tau) \) in the three-dimensional free space:

\[
\frac{\partial \varepsilon}{\partial \tau} = \nabla^2 \varepsilon \quad \text{for} \quad x \in \mathbb{R}^3, \tau > 0 \tag{9}
\]

\[
\varepsilon(x, 0) = \varepsilon_0(x) \tag{10}
\]

where \( x \equiv [x, y, z]^T \) are spatial coordinates; \( \varepsilon \) can be considered as solid volume fraction \( \varepsilon_s \), but the derivations below are valid for other coarse-grained quantities (e.g., \( U_s \) and \( F_s \)) as well. Diffusion equations are independently solved for each component when the coarse grained fields are vector- and tensor-fields. For simplicity, the subscript \( s \) of \( \varepsilon \) is omitted in this subsection. \( \nabla^2 \varepsilon = \frac{\partial \varepsilon}{\partial x^2} + \frac{\partial \varepsilon}{\partial y^2} + \frac{\partial \varepsilon}{\partial z^2} \) in the Cartesian coordinate; \( \varepsilon_0(x) \) is a square integrable function; \( \tau \) is pseudo-time (time divided by a unit diffusion coefficient), which should be distinguished from the physical time \( t \) in the CFD–DEM formulation. To solve the problem above, we recall that the fundamental solution (also called Green’s function) of the diffusion equation in free space is [e.g., 50, Chapter 11]:

\[
G(x, \tau) = \frac{1}{(4\pi \tau)^{3/2}} \exp\left[-\frac{x^T x}{4\tau}\right], \tag{11}
\]
which is basically the solution to Eq. (9) with the initial condition \( \varepsilon(x,0) = \delta(x) \), with \( \delta(x) \) being Dirac delta function. Based on the Green’s function, the solution to Eq. (9) with initial conditions in Eq. (10) is:

\[
\varepsilon(x,\tau) = \int_{\mathbb{R}^3} G(x - \xi, \tau) \varepsilon_0(\xi) d\xi.
\] (12)

Consider the initial condition consisting of a linear combination of \( N_p \) shifted delta functions centered at \( x_i \), where \( i = 1, \cdots, N_p \), that is,

\[
\varepsilon_0(x) = \sum_{i=1}^{N_p} V_{p,i} \delta(x - x_i),
\] (13)

where \( V_{p,i} \) are multiplier coefficients for each shifted delta function. The interpretation of \( V_{p,i} \) as particle volume and \( N_p \) as number of particles will be evident shortly. Plugging in Eq. (13) to Eq. (12) yields the solution to the diffusion equation (9) with the initial condition of superimposed shifted delta functions:

\[
\varepsilon(x,\tau) \equiv \sum_{i=1}^{N_p} \varepsilon_i = \sum_{i=1}^{N_p} V_{p,i} G(x - x_i, \tau),
\] (14)

which is a linear combination of the \( N_p \) Green functions. This is illustrated in Fig. 6.

Consider the solution at a fixed pseudo-time \( \tau = T \), denoted as \( \hat{\varepsilon}(x) \equiv \varepsilon(x,T) \). The solution is rewritten as:

\[
\hat{\varepsilon}(x) = \sum_{i=1}^{N_p} V_{p,i} G_i,
\] (15)

where

\[
G_i = G(x - x_i) = \frac{1}{(4\pi T)^{3/2}} \exp \left[ -\frac{(x - x_i)^T (x - x_i)}{4T} \right].
\] (16)

Comparing Eqs. (15) and (16) with Eqs. (2) and (3), the equivalence between diffusion based and the statistical kernel based coarse graining is established with \( b = \sqrt{4T} \). The physical interpretation is that given \( N_p \) particles centered at \( x_i \) with volume \( V_{p,i} \), the following two ways of calculating solid volume fraction field are equivalent:

1. compute the solid volume fraction field \( \varepsilon_0 \) by using the PCM, and solve Eq. (9) until \( \tau = T \) with \( \varepsilon_0 \) as initial condition; and
Figure 6: The solution to the diffusion equation with a linear combination of shifted delta functions as initial conditions. The initial condition $\varepsilon(\tau = 0)$ is obtained from the procedure of the PCM; $\varepsilon_i(\tau = T)$ are the diffused solutions corresponding to each shifted delta functions; $\varepsilon(T)$ is the superposition of $N_p$ Green’s functions, which is the result obtained with the proposed coarse graining procedure.

2. use the Gaussian kernel based coarse graining according to Eqs. (15) and (16) with bandwidth $b = \sqrt{4T}$.

3.2.2. Treatment of Physical Boundaries

The equivalence shown above holds for interior domains where boundary effects are not present. For particles near boundaries, we consider the same diffusion equation as Eq. (9) on a semi-infinite domain $D = \{(x, \tau) | P(x) \geq 0, \tau > 0\}$, where $P(x) = 0$ is the equation of the boundary plane. Zero-gradient Neumann boundary condition, i.e., $\partial \varepsilon / \partial n = 0$, is specified at the boundary, where $n$ is the normal direction of the plane.

The solution to Eq. (9) at time $\tau = T$ with initial condition

$$\varepsilon_0 = \sum_{i=1}^{N_p} V_{p,i} \delta(x - x_i)$$

can be obtained by constructing a Green’s function that satisfy the zero-gradient condition on the boundary plane. It turns out that such a Green’s function,
denoted as $\tilde{G}_i$, can be found by the method of images [50]:

$$\tilde{G}_i = G(x - x_i, T) + G(x - x'_i, T) = \frac{1}{(4\pi T)^{3/2}} \left( \exp \left[ -\frac{(x - x_i)^T(x - x_i)}{4T} \right] + \exp \left[ -\frac{(x - x'_i)^T(x - x'_i)}{4T} \right] \right), \quad (18)$$

where $x'_i$ is the image of $x_i$ with respect to the boundary plane $P(x) = 0$. The solution to the diffusion equation on a domain bounded by plane $P(x) = 0$ is:

$$\hat{\varepsilon}(x) = \sum_{i=1}^{N_p} V_{p,i} \tilde{G}_i. \quad (19)$$

Clearly, the solution $\tilde{G}_i$ is equivalent to the kernel function $\tilde{h}_i$ in Eq. (5) when $b = \sqrt{4T}$.

The equivalence can be extended to the general case where the domain is bounded in all three directions and a particle is located near the corner, i.e., it is close to many, possibly non-orthogonal boundary planes (see Fig. 5). On such a domain, with no-flux boundary conditions the Green’s function for the diffusion equation is a summation of infinite series [50]:

$$\tilde{G}_i = \sum_{n=0}^{\infty} G^{(n)}(x - x_i, T), \quad (20)$$

which corresponds exactly with the summation of infinite series of kernel functions in Eq. (12). This is not surprising since this solution is obtained with the method of images, which is the same idea based on which the kernel function in Eq. (12) is obtained. In summary, the diffusion-based coarse graining procedure as described in Section 3.1 is theoretically equivalent to the statistical kernel method presented in Section 2.5.

Numerically the equivalence between the two methods holds up to the mesh discretization accuracy. If the mesh used to obtain $\varepsilon_0$ is sufficiently small, or equivalently, if the initial condition obtained via PCM used for the diffusion equation is approximately a linear combination of shifted delta functions corresponding to individual particles, then the two methods are numerically equal. We emphasize that the diffusion-based method can handle both particles in the interior domain and those near the boundaries in a unified manner, i.e., by solving a diffusion
equation with no-flux boundary conditions. The equivalence to statistical kernel function is valid for domains of arbitrary shapes, for both interior particles and particles close to arbitrary boundaries. This characteristics of the current method distinguishes itself from its theoretically equivalent counterpart, the statistical kernel-based coarse graining, where obtaining the Green’s functions for particles located near corners in a generic three-dimensional domain can be tedious.

4. A Priori Numerical Tests

In this section, the diffusion-based coarse graining algorithm described in Section 3 is used to obtain coarse grained solid volume fraction $\varepsilon_s$ fields given a quasi-random distribution of particles in the computational domain. Note that even though we occasionally refer to “CFD mesh” in the text, no CFD or DEM simulations are performed in these tests, and the particles do not move.

In Section 4.1, we first compare the coarse grained $\varepsilon_s$ fields obtained by using the diffusion-based method and those obtained with Gaussian kernel functions to verify the theoretical equivalence of the two shown in Section 3.2. In some CFD–DEM simulations, the flow field resolution requirements may necessitate using cells that are comparable to or smaller than the particle diameters in certain regions. As a consequence, using CFD mesh for coarse graining as is done in PCM and DVPM can lead to two potential problems: unphysically large $\varepsilon_s$ in small cells and mesh-dependent $\varepsilon_s$ fields. To demonstrate the merits of the proposed method, tests in Sections 4.2–4.4 aim to show its capabilities to produce smooth coarse grained fields on meshes with small cells, to handle stretched and unstructured meshes, and to produce mesh-independent results. Comparisons are made with other coarse graining methods when applicable.

All simulations presented below are performed with 1000 spherical particles with quasi-random spatial distribution in the computational domain. In the verification tests presented in Section 4.1, two representative distributions of particles are used to evaluate the performance of the proposed method for particles located in interior cells and those located near boundaries. The two configurations are
displayed in Figs. 7(a) and 7(b), respectively. In both cases the sizes of the domain are \( L_x \times L_y = 135d_p \times 135d_p \), where \( L_x \) and \( L_y \) are the dimensions in \( x \) and \( y \) directions, respectively. Simulations are performed on meshes with only one layer of cells in \( z \)-direction. The thickness of the cells is the same as the particle diameter, and all particles are located on the same plane normal to the \( z \)-axis. No-flux conditions are specified at all boundaries to ensure conservation of particle mass in the coarse graining procedure.

![Figure 7: Distribution of particles in computational domain showing particles located in (a) interior cells and (b) near-boundary cells. The size of the computational domain is \( L_x \times L_y = 135d_p \times 135d_p \) (dimensions in \( x \) and \( y \) directions, respectively). Shades indicate regions of interests, coarse graining fields for which will be presented in subsequent plots. Thick lines indicated the boundaries of the computational domain.](image)

4.1. Verification of Equivalence to Gaussian Kernel Coarse Graining

In this test, solid volume fraction field is obtained from the particle distribution by using both statistical kernel coarse graining and the diffusion-based method to demonstrate the equivalence between the two. The mesh resolution is \( N_x \times N_y = 45 \times 45 \), where \( N_x \) and \( N_y \) are the numbers of cells in \( x \) and \( y \) directions,
respectively. The bandwidth $b$ used for the statistical kernel method is $6d_p$, and the corresponding diffusion time $T$ is $9d_p^2$ for the diffusion-based method according to $b = \sqrt{4T}$. This test is performed for both interior particles and near-boundary particles.

For interior particles, the solid volume fraction fields along the centerline of the domain (indicated by the dashed line in Fig. 8(a)) obtained by using both methods are displayed in Fig. 8. The domain of interest (shaded region in Fig. 7(a)) is shown in Fig. 8(a), and the coarse grained $\varepsilon_s$ fields are presented in Fig. 8(b). It can be seen that the $\varepsilon_s$ fields obtained by using statistical kernel-based coarse graining and that by using the diffusion-based method agree very well. For the configuration with particles located near boundaries as shown in Fig. 7(b), the mesh and detailed particle distribution are shown in Fig. 9(a), and Fig. 9(b) displays the $\varepsilon_s$ fields obtained by using both methods. Again, that the coarse grained $\varepsilon_s$ fields in the simulation using both methods are consistent.

From the results above, it can be seen that the statistical kernel method with Gaussian kernels and the proposed method are indeed equivalent for both interior and near-boundary particles. Note that the boundary effect is accounted for in the Gaussian kernel coarse graining by using the image kernels in Eq. (5). While the kernel function in the statistical kernel method needs to be modified to accommodate the proximity of particles to the boundary (see Section 2.5.2), the diffusion-based method remains the same for both the interior and the near-boundary particles by using no-flux boundary conditions. This simplicity in formulation and implementation is an important improvement of the proposed method over statistical kernel-based coarse graining method.

4.2. Comparison with Existing Coarse Graining Methods

To demonstrate the advantages of the diffusion-based coarse graining method, the comparison of the diffusion-based method with PCM, DPVM, and two-grid formulation is performed. The set-up and parameters, including the computational domain, mesh resolution, particle distribution, bandwidth, diffusion time are the same as in Section 4.1. Since the performances of these coarse graining methods are
Figure 8: Equivalence between statistical kernel method and diffusion-based method for interior particles, showing (a) the particle distribution and the mesh used for the coarse graining, and (b) the solid volume fraction along the dashed line indicated in panel (a). The same bandwidth $b = 6d_p$ is used for both methods.

Figure 9: Equivalence between statistical kernel method and diffusion-based method for near-boundary particles, showing (a) the particle distribution and the mesh used for the coarse graining, and (b) the solid volume fraction along the dashed line indicated in Panel (a).
similar for both interior and near-boundary particles, only the results for interior particles are presented below.

Figure 10 shows the comparison of the $\varepsilon_s$ fields obtained by using PCM, DPVM, and the diffusion-based method. It can be seen that the largest $\varepsilon_s$ in the $\varepsilon_s$ field computed by PCM is 0.64, which is clearly unphysical as it exceeds the maximum possible value (0.606) for close-packed spherical particles in a two-dimensional domain [51]. This is attributed to the inaccuracy of the PCM when the centroid of a particle is located near the boundaries of a cell as discussed in Section 2.2. The maximum $\varepsilon_s$ value in the DPVM results is smaller than that of PCM, since the volume of a particle is divided among all cells it intersects with. Although the $\varepsilon_s$ field obtained by using DPVM is smoother than the PCM results, the overall fluctuations and gradients are still large. Considering the statistically uniform particle distribution in the domain, which is evident from visual observations of Fig. 8(a), these fluctuations cannot be justified physically, and thus are considered artifacts introduced by the coarse graining procedure. In contrast, the $\varepsilon_s$ field obtained by using the diffusion-based method is much smoother with a flat region in the middle (between $x/d_p = 50$ and 80), confirming the visual observation of statistically uniform particle distribution near the core of the region occupied by the particles.

The comparison of diffusion-based method and two-grid formulation is presented in Fig. 11. The configuration of the coarse graining mesh is displayed in Fig. 11(a), showing that each cell in the coarse graining mesh contains exactly $3 \times 3$ CFD cells. From the $\varepsilon_s$ profiles along the horizontal centerline presented in Fig. 11(b), both methods are able to produce smooth solid volume fraction fields that are consistent with each other. Noted that the resolution of the coarse graining mesh for two-grid formulation is lower than that of the CFD mesh (with much larger cells), which explains why the results obtained by with the diffusion-based method is smoother. The $\varepsilon_s$ values on the CFD mesh is not directly obtained, and interpolations (also called mapping) from the coarse-graining mesh to the CFD mesh are needed to obtain $\varepsilon_s$ in CFD cells [40]. Linear interpolation is used...
Figure 10: Comparison of coarse-grained solid volume fraction obtained by using PCM, DPVM, and diffusion-based coarse graining method. Shown is the solid volume fraction along the horizontal centerline of the domain indicated by the dashed line in Fig. 8(a).

to obtain the results presented in Fig. 11(b). In contrast, in the diffusion-based method the coarse grained $\varepsilon_s$ field is obtained directly on the fine mesh without the need of interpolations between two meshes. Another problem in the implementation of the two-grid formulation is the agglomeration of the unstructured mesh, which has been discussed in Section 2.4. Therefore, despite the fact that the two methods give consistent coarse grained $\varepsilon_s$ fields in this case, we argue that the diffusion-based method is preferred when used in general CFD solvers due to its straightforward implementation on arbitrary meshes.

To summarize the comparison, solid volume fraction contours in the two-dimensional domain obtained by using the four methods, PCM, DPVM, two-grid formulation, and diffusion-based method, are presented in Fig. 12. In these plots, each cell is colored according to the corresponding $\varepsilon_s$ value in the cell, and no interpolations are used to obtain the contours. Consequently, the meshes used in each case (presented above) are clearly distinguishable from the plots. As is evident from the contours, extreme high or low values (and thus large gradients) are most frequent in the PCM results, and also occasionally occur in the DPVM result. In contrast, no such extreme values are present in the plot obtained with
the two-grid formulation and that from the diffusion-based method. In the two-grid formulation result, all CFD cells in the same coarse graining cell have the same $\varepsilon_s$ value due to the simple mapping scheme used (following ref. [40]).

Figure 11: Comparison of the diffusion-based coarse graining method and the two-grid formulation. Panel (a) displays the mesh and the particle distribution in the shaded region of Fig. 7(a). Each cell in the coarse graining mesh, indicated in thick lines, contains exactly $3 \times 3$ CFD cells. Although CFD simulations are not performed here, the mesh is used for the coarse graining with the diffusion-based method. Panel (b) shows the solid volume fraction along the horizontal centerline of the domain (dashed line in panel (a)).

4.3. Coarse Graining on Stretched and Unstructured Meshes

In this subsection, the performance of the diffusion-based coarse graining method is evaluated on a stretched mesh and an unstructured mesh with triangular cells. These types of meshes are commonly used in industrial CFD simulations. Since these highly irregular meshes pose difficulties in the coarse graining procedure, this is an illustration of the merits of the diffusion-based method. The computational set-up and parameters are the same as used in Section 4.1. The coarse grained $\varepsilon_s$ field obtained by using the uniformly spaced mesh presented in Fig. 8(a) is used as benchmark solution for comparison purposes.
Figure 12: Comparison of the solid volume fraction $\varepsilon_s$ fields obtained by using the four coarse graining method: (a) PCM, (b) DPVM, (c) the two-grid formulation, and (d) the diffusion-based method. The particle distribution and the meshes used to obtain the plots for PCM, DPVM, and the diffusion-based method are shown in Fig. 8(a) and those for the two-grid formulation are shown in Fig. 11(a).
Figure 13(a) shows the particle locations on top of the stretched mesh. The mesh has \( N_x \times N_y = 90 \times 45 \) cells with progressive refinement in \( x \)-direction towards the vertical centerline, and the stretch ratio, defined as the ratio between the widths of two adjacent cells, is 1.04. The coarse grained solid volume fraction along the horizontal center line is presented in Fig. 13(b). It can be seen that \( \varepsilon_s \) profile obtained by using the diffusion-based method on the stretched mesh are identical to that from the uniform mesh. This demonstrates the capability of the diffusion-based method in performing coarse graining on stretched meshes without causing computational artifacts.

![Graphs showing mesh and particle distribution and solid volume fraction](image)

Figure 13: Comparison between solid volume fraction obtained with uniform mesh and stretched mesh using diffusion-based coarse graining method. Panel (a) displays the mesh and the particle distribution in the shaded region in Fig. 7(a). The mesh is stretched in \( x \)-direction with a resolution of \( N_x \times N_y = 90 \times 45 \). Panel (b) shows the solid volume fraction along the horizontal centerline of the domain (dashed line in panel (a)).

The coarse graining test on an unstructured mesh with triangular cells are shown in Fig. 14. Figure 14(a) illustrates the particle distribution and the unstructured mesh, with a close-up view of part of the computational domain shown in the inset. The obtained solid volume fraction along the horizontal center line is shown in Fig. 14(b). It can be seen that the coarse grained \( \varepsilon_s \) profile obtained on
the unstructured mesh is consistent with that obtained on the structured mesh.

It is worth mentioning that it would be difficult for other coarse graining methods to obtain smooth $\varepsilon_s$ fields for stretched or irregular meshes as the ones shown in Figs. 13(a) and 14(a). Generally speaking, compared to the methods that use an independent mesh or parameter for coarse graining (e.g., two-grid formulation and statistical kernel method), the methods that directly use the CFD mesh for coarse graining (e.g., PCM and DPVM) are more susceptible to the spatial variations (e.g. stretching) in the CFD meshes, which are often done for the purpose of accommodating flow features or complex geometries of computational domains in CFD simulations. In contrast, the proposed method is relatively independent of the CFD mesh as demonstrated above, despite the fact that it uses the CFD mesh for coarse graining. In summary, the two tests here suggest that the diffusion-based coarse graining method can produce smooth $\varepsilon_s$ fields even on meshes with significant stretching and on unstructured meshes with very small cells.

Figure 14: Comparison of solid volume fractions obtained by using the diffusion-based coarse graining method on structured and unstructured meshes. Panel (a) displays the mesh and the particle distribution in the shaded region of Fig. 7(a), with an inset showing a close-up view of a small region. The solid volume fraction profile along the horizontal centerline of the domain is shown in panel (b).
4.4. Mesh Convergence Study

As stated in Section 2.1, a highly desirable property of a coarse graining algorithm is being able to yield mesh-independence coarse graining fields, where the mesh here refers to CFD mesh. Part of the mesh-independence has been studied in Section 4.3 above. This subsection focuses on the convergence of results on progressively refined meshes. As reviewed in Section 2 (see Table 1 for a summary), statistical kernel function methods and the two-grid formulation can give relatively mesh-independent results, since the bandwidth (for the statistical kernel methods) or mesh (for the two-grid formulation) used for coarse graining can be chosen independently of the CFD mesh. In contrast, PCM and DPVM use the CFD mesh for coarse graining, and thus the coarse grained fields so obtained inevitably depend on the CFD mesh used. The purpose of this test is to demonstrate the mesh convergence characteristics of the diffusion-based coarse graining method.

The particle distribution and the computational domain size are the same as above as shown in Fig. 7(a). The coarse grained $\varepsilon_s$ fields are obtained by using the diffusion-based method with four successively refined meshes A, B, C, and D, the resolution and cell sizes for which are presented in Table 2. Note that in the finest mesh D, the volume of each cells is $0.25d_p^2$, which is only about half of the volume of a spherical particle of diameter $d_p$. When the volume of a cell is smaller than the particle, and if PCM is used to obtain the solid volume fraction, the $\varepsilon_s$ value would be larger than one for the cells in which the particle centroids are located; for DVPM, the cells that are fully occupied by a particle would have $\varepsilon_s$ values equal to one. Even though such scenarios may only occur in a few cells, it can lead to very large fluid drag forces on the particles and on the fluid, ultimately destabilizing the simulation.

The coarse grained $\varepsilon_s$ fields obtained by using the diffusion-based method on meshes A–D are presented in Fig. 15(a). It can be seen that the coarse grained $\varepsilon_s$ fields along the horizontal centerline obtained with the three finer meshes B, C and D are identical (as demonstrated by the lines falling on top of each other),
suggesting that mesh convergence is achieved. The very minor deviation of the results from mesh A ($\Delta x = 4d_p$) near $x/d_p = 75$ is due to the slightly inadequate mesh resolution, and this is expected. Also note from Fig. 15 that unphysically large \(\varepsilon_s\) values do not appear in any of the coarse grained \(\varepsilon_s\) fields produced by the diffusion-based method, even for the finest mesh D ($\Delta x = 0.5d_p$), which has cell volumes smaller than the volume of a single particle as explained above. For comparison purposes, the coarse grained \(\varepsilon_s\) fields obtained by using PCM and DPVM are presented in Figs. 15(b) and 15(c), respectively. Only the results from meshes A–C are shown for these two cases, and the results for mesh D are omitted. This is due to the presence of excessively large \(\varepsilon_s\) values on the mesh D results, and also because PCM and DPVM are not expected to work on meshes with cell dimensions smaller than the particle diameter. From Figs. 15(b) and 15(c) it can be seen that with PCM and DPVM the coarse grained solid volume fraction values exhibit more spatial oscillations as the mesh is refined, producing more extreme high and low values (e.g., high values over 0.7 and low values of 0 in mesh C for both cases). Mesh convergences is not achieved for either methods. Although it is not presented here, it is expected that the two-grid formulation should be able to give mesh-independent results, as long as the same mesh (e.g., mesh A) is used for as the coarse-graining mesh same for the all cases. In this case, the coarse-graining mesh would contain 1 × 1, 2 × 2, 4 × 4, and 8 × 8 CFD cells, respectively, for cases A, B, C, and D.

Hence, from the results obtained in the mesh convergence test and those presented in Section 4.3, we can conclude that the diffusion-based method is able to produce smooth and mesh-independent coarse grained fields, even for very fine meshes with cells that are smaller than the particles or meshes with stretching. This is a significant advantage over PCM and DPVM, and would have profound implications in CFD–DEM simulations.

5. Discussion

The proposed coarse graining method involves solving transient diffusion equations, which is straightforward, and can usually take advantage of the existing in-
Figure 15: Mesh independence test of the proposed method, showing the coarse grained solid volume fraction $\varepsilon_s$ fields along the horizontal centerline of the domain (indicated by the dashed line in Fig. 8(a)) for (a) diffusion-based method, (b) PCM, and (c) DPVM. The study is performed on four successively refined meshes A–D, with the cell dimensioned and the numbers of cells presented in Table 2. The results for PCM and DPVM on the finest mesh ($\Delta x = 0.5d_p$) are omitted due to the presence of excessively large $\varepsilon_s$ values, and also because these two methods are not expected to work on this mesh with $\Delta x$ smaller than the particle diameter $d_p$. 

37
Table 2: Parameters for the four successively refined meshes used in the mesh-convergence study

| mesh | $\Delta x$ and $\Delta y$ | $N_x$ and $N_y$ |
|------|---------------------------|-----------------|
| A    | $4d_p$                    | 35              |
| B    | $2d_p$                    | 69              |

The infrastructure (e.g., discretization schemes, linear system solvers, parallel computing capabilities) available in the CFD solver. In this work, the implementation of the diffusion equation solver in OpenFOAM and its integration into the CFD–DEM solver needed only a few dozen lines of additional code.

A second-order central scheme was used for the spatial discretization in the diffusion equation; the Crank–Nicolson scheme was used for temporal integration. With this choice of discretization schemes the stability is guaranteed for any time step size due to the implicit nature of the time stepping. Therefore, the time step size is only restricted by the solution accuracy to be achieved. It is noted that the accuracy in solving the diffusion equations is not essential for the coarse graining. One can consider that an inaccurate temporal or spatial discretization of the diffusion equation leads to a solution corresponding to a modified equation, which may have a different diffusion constant (corresponding to a different kernel bandwidth) than specified, or even a different way of coarse graining. However, slight inaccuracies are acceptable, since the coarse graining scheme used to link microscopic and macroscopic variables is non-unique anyway. Hence, for the sake of reducing computational costs, large time step sizes can be used to solve the diffusion equations in the coarse graining.

In this study it was found that using only three or even one time step, i.e., a time step size of $\Delta \tau = T/3$ or $T$, was sufficient. Figure 16 displays the coarse grained $\varepsilon_s$ field obtained with different time step sizes $\Delta \tau = T/8$, $T/3$, and $T$. 

38
It can be seen that the $\varepsilon_s$ fields obtained in the three case are almost identical. The particle configuration presented in Fig. 8(a) was used in this calculation. The number of time steps needed to solve the diffusion equation with a given accuracy also depends on the time span $T$ or the bandwidth $b$. The bandwidth used in obtaining the results in Fig. 16 was $b = 6d_p$. Bandwidths up to $b = 24d_p$ have been tested, and even with such a excessively large bandwidth, a time step size of $\Delta \tau = T/3$ or $T$ still yielded qualitatively similar results as presented in Fig. 16. The kernel bandwidth $b$ is a physical parameter usually specified based on the particle diameters $d_p$. In particular, note that the bandwidth $b$ is chosen independent of the CFD mesh sizes.

6. Conclusion

In this work, we proposed a coarse graining algorithm based on solving diffusion equations with no-flux boundary conditions. The coarse graining method is valuable for coupled continuum–discrete solvers such as CFD–DEM solvers for dense particle-laden flows. The proposed algorithm can be straightforwardly implemented in any parallel, three-dimensional mesh-based CFD solvers developed for industrial flow simulations on complex geometries. Via theoretical analysis we demonstrated that the proposed method was equivalent to the statistical Gauss-
ussian kernel-based coarse graining method. The equivalence is established for both interior particles and particles near boundaries, and is valid for domains of arbitrary domain shapes up to the mesh discretization accuracy. The theoretical equivalence was verified by using several a priori numerical tests. It was further demonstrated that the proposed algorithm was able to yield physically reasonable, spatially smooth coarse grained fields on stretched meshes, unstructured meshes, and meshes having cells with volumes smaller than the volume of a particle. Moreover, numerical tests on successively refined meshes showed that the diffusion-based coarse graining method was able to produce mesh-independent results, which is an important advantage over many existing coarse graining methods such as the particle centroid method and the divided particle volume method.

In summary, the merits of the proposed coarse graining method include (1) sound theoretical foundation, (2) unified treatment of interior and near-boundary particles within the same framework, (3) guaranteed conservation of relevant physical quantities (e.g., particle mass in the cases demonstrated) in the coarse graining procedure, (4) easy implementation in CFD solvers with almost arbitrary meshes and ability to produce smooth and mesh-independent coarse-grained fields on unfavorable meshes, and (5) easy parallelization by utilizing the existing infrastructure in the CFD solver. The diffusion-based coarse graining method has been implemented into a CFD–DEM solver, the results of which will be presented in a separate work.
