Impact of a Light Strange-Beauty Squark on $B_s$ Mixing and Direct Search

(March 25, 2022)

If one has Abelian flavor symmetry, $s_R$-$b_R$ mixing could be near maximal. This can drive a “strange-beauty” squark ($s_R$) to be rather light, but still evade the $b \to s\gamma$ constraint. Low energy constraints imply that all other superpartners are at TeV scale, except for a possibly light neutralino, $\tilde{\chi}_1^0$. Whether light or heavy, the $s_R$ can impact on the $B_s$ system: $\Delta m_B$, and indirect CP phase, even for $B_s \to \phi\gamma$. Direct search is similar to usual $b \to sB^0\gamma$, but existing bounds are weakened by $s_R \to s\chi_1^0$ possibility. All these effects could be studied soon at the Tevatron.

The source of CP violation within the Standard Model (SM) rests in the flavor sector, which is not well understood. With three quark generations, we have 6 masses, 3 mixing angles and a unique CP phase in the Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix $V$. Together with leptons, the majority of SM parameters in fact lies in the flavor sector. However, the left-handed nature of weak dynamics screens out the mixings and CP. The actual number of flavor parameters are much larger than meets the eye!

The observed quark masses and mixings do, however, exhibit an intriguing hierarchical pattern in powers of $\lambda \equiv |V_{us}|$, hinting at a possible underlying symmetry [1]. If this “horizontal” or flavor symmetry is Abelian, then $s_R$-$b_R$ mixing would be near maximal [2,3], although still hidden from view. It is interesting that, if supersymmetry (SUSY) is also realized, $s_R$-$b_R$ squark mixing could then be near maximal. This could generate observable effects in $b \to s$ transitions even if squark masses are at TeV scale [2,3]. Furthermore, one of the squarks, the “strange-beauty” squark $\tilde{s}_R$, could be driven by this large flavor violation to be considerably below the other squarks [3]. Whether we have a light $\tilde{s}_R$ squark or not, it is of great interest since the current bound on $\Delta m_{B_s}$ [4] indicates that it could be larger than SM expectations.

In this Letter we point out that a light $\tilde{s}_R$ squark and a light neutralino $\tilde{\chi}_1^0$ are allowed by the $b \to s\gamma$ constraint. We explore the implications of large $s_R$-$b_R$ mixing on $B_s$-$B_s$ mixing and its CP phase $\Phi_{B_s}$. In case of light $\tilde{s}_R$, we briefly comment on direct search. All these effects can be covered at the Tevatron Run II, which has just started. Mixing dependent CP violation in $B_s \to \phi\gamma$ decay can also be studied in the future. We stress that, besides the assumptions of Abelian flavor symmetry and SUSY, the quark mixing and CP phase we study are on similar footing as the usual CKM matrix.

Horizontal models try to explain the mass and mixing hierarchies by powers of $\lambda \sim \langle S \rangle / M$, where $\langle S \rangle$ is the expectation of a scalar field $S$ and $M$ is a high scale. For Abelian symmetries, the commuting nature of horizontal charges in general gives $M_iM_{ij} \sim M_{ij}M_i$ (i, j not summed), where “$\sim$” indicates approximate rather than exact equality. This allows one to determine, e.g., $M_d^{23}$ from our knowledge of $M_d^{22} \sim m_s \lambda^2 m_b$, $M_d^{23} \sim V_{23}m_b \lambda^2 m_b$ and $M_d^{33} \sim m_b$. Hence [4]

$$\tilde{M}_d = \frac{M_d}{m_b} \sim \begin{bmatrix} \lambda^2 & [\lambda^3] & [\lambda^3] \\ [\lambda] & 1 & 1 \\ [\lambda] & 1 & 1 \end{bmatrix},$$ (1)

and similarly for $M_u$; the $[\cdots]$ terms would be set to zero as explained shortly. Diagonalizing $\tilde{M}_d$ by a biunitary $D_L$ and $D_R$ transform, $D_R^{23} \sim 1$ is clearly the largest mixing element, but its effect is hidden within SM.

Taking SUSY as commuting with the horizontal symmetry, the squark mass matrices are fixed by the common horizontal charge of the chiral supermultiplet. We take the usual approach that squarks are almost degenerate with common scale $\tilde{m}$. From Eq. (1) one finds that $(\tilde{M}_d^2)_{LR} = (\tilde{M}_d^2)^{11}_{LR} \sim \tilde{m}M_d$, $(\tilde{M}_d^2)^{11}_{LL} \sim \tilde{m}^2 V$, while

$$\tilde{(M}_d^2)_{RR} \sim \tilde{m}^2 \begin{bmatrix} 1 & [\lambda] & [\lambda] \\ [\lambda] & 1 & 1 \\ [\lambda] & 1 & 1 \end{bmatrix},$$ (2)

where $(\tilde{M}_d^2)^{23,32} \sim \tilde{m}^2$ if $s_R$ and $b_R$ have the same horizontal charge(s), hence comparable to $(\tilde{M}_d^2)_{RR}^{23,32} \sim \tilde{m}^2$.

We are interested in the impact of $(\tilde{M}_d^2)_{RR}^{23,32}$. It is known that 4 texture zeros are needed [3] to fully evade the $\Delta m_K$ and $\epsilon_K$ constraints. Hence, we choose horizontal charges such that the $[\cdots]$ terms in Eqs. (1) and (2) are all set to zero, which is achievable under a U(1)×U(1) or higher horizontal group. With the $d$ quark thus decoupled, one is safe from all known low energy constraints. However, one needs $(\tilde{M}_d^2)^{12,21}_{LL} \sim \lambda\tilde{m}^2$ to account for $V_{us}$ [4]. It is intriguing that $\tilde{m}$, $m_g \sim$ TeV brings [4] $\Delta m_{D}$ right into the ballpark of current [6] experimental sensitivities. This sets the scale for $\tilde{m}$ and $m_g$, for if they were lighter, $\Delta m_{D}$ would be too large. Similarly, $\Delta m_{K}$ constrains $\tilde{u}_L$, $\tilde{c}_L$ and $\tilde{\chi}^\pm$ loops, implying also [4]

$$\tilde{(M}_d^2)_{RR} \sim \tilde{m}^2 \begin{bmatrix} 1 & [\lambda] & [\lambda] \\ [\lambda] & 1 & 1 \\ [\lambda] & 1 & 1 \end{bmatrix},$$ (2)

where $(\tilde{M}_d^2)^{23,32} \sim \tilde{m}^2$ if $s_R$ and $b_R$ have the same horizontal charge(s), hence comparable to $(\tilde{M}_d^2)_{RR}^{23,32} \sim \tilde{m}^2$.

that squarks are at TeV scale, while the wino part of the chargino is heavier than 500 GeV.

With $d$-flavor decoupled, the $s$-$b$ part of $\tilde{M}_{RR}^2$ in Eq. (2) appears “democratic”. More explicitly, one has

$$\tilde{M}_{RR}^{2(sb)} = \left[ \begin{array}{cc} \tilde{m}_{22}^2 & \tilde{m}_{22}^2 e^{-i\sigma} \\ \tilde{m}_{23}^2 e^{i\sigma} & \tilde{m}_{33}^2 \end{array} \right] = R \left[ \begin{array}{cc} \tilde{m}_1^2 & 0 \\ 0 & \tilde{m}_2^2 \end{array} \right] R^\dagger \label{eq:3}$$

in quark mass basis, where $\tilde{m}_{ij}^2 \sim \tilde{m}_i^2$ are all $> 0$, and

$$R = \left[ \begin{array}{cc} c_\theta & s_\theta e^{i\sigma} \\ -s_\theta e^{-i\sigma} & c_\theta \end{array} \right]. \label{eq:4}$$

The phase in $R$ absorbs the $\sigma$ phase in $\tilde{M}_{RR}^{2(sb)}$, which is on similar footing as $\phi_3 \equiv \arg V^\dagger_{ub}$. By way of $\tilde{m}_{22}^2 \sim \tilde{m}_{23}^2 \sim \tilde{m}_{33}^2$, in general we have one suppressed eigenvalue $\tilde{m}_1^2$ due to level splitting, where $\theta$ is a measure of the relative weight of $\tilde{m}_{23}^2$ vs $\tilde{m}_{33}^2 - \tilde{m}_{22}^2$. Since our case corresponds to $\tilde{m}_{22}^2 \approx \tilde{m}_{23}^2 \approx \tilde{m}_{33}^2 \approx \tilde{m}_2^2$ because of Eqs. (1) and (2), near maximal mixing is implied. The eigenstates hence carry both $s$ and $b$ flavors and are called the strange-beauty squarks $\tilde{s}_b, \tilde{b}_s$. Without much loss of generality, we take $\tilde{m}_{22}^2 = \tilde{m}_{23}^2 = \tilde{m}_2^2$ (so $\theta = \pi/4$ and $\tilde{m}_1^2 + \tilde{m}_2^2 \approx 2\tilde{m}_2^2$) and consider the ratio $\tilde{m}_{23}^2/\tilde{m}_2^2 \equiv 1 - \delta \approx 1$. The squark mass eigenvalues must be positive to preserve color symmetry, hence $\delta > 0$ is required. For small $\delta$, we have $\tilde{m}_1^2 \approx \delta \tilde{m}_2^2$ and $\tilde{m}_3^2 \approx (2 - \delta)\tilde{m}_2^2$. Thus, with some tuning, $\tilde{s}_b$ can become quite light, i.e. $\tilde{m}_1^2 \ll \tilde{m}_2^2 \approx 2\tilde{m}_2^2$, the driving force being the large $(\tilde{M}_{\ell LR}^{23,32}/\tilde{m}_2^2 \sim 1$ in Eqs. (2) and (3). We note that, assuming $\tilde{m} \sim 2$ TeV, tuning $\delta$ to $\delta^2, \delta^3, \delta^4$ give $\tilde{m}_1 = 440, 206, 97$ GeV; for $\tilde{m} \sim 1$ TeV, $\delta = \lambda$, $\delta^2, \delta^3$ give $\tilde{m}_1 = 470, 220, 103$ GeV. In the following, we limit ourselves to $\tilde{m}_1 \geq 100$ GeV.

Besides concerns about tuning, the pressing question is that a light $\tilde{s}_b$ driven by large strange-beauty mixing seems particularly dangerous in face of the $b \to s\gamma$ constraint. As shown in [2], heavy squark and gluino loops are suppressed by $1/G_\text{FM} \tilde{m}_2^2$ compared to SM contribution, such that $b \to s\gamma$ rate is hardly affected. It is interesting that, even with $\tilde{s}_b$ as light as 100 GeV, the $b \to s\gamma$ constraint is still rather accommodating.

Since mass splittings are large, the calculation of short distance coefficients is done following [4]. The expressions for Wilson coefficients together with their renormalisation group equations (RGE) can be found in [3]. Our model gives large RR and RL mixings, while LL and LR mixings are suppressed by $\lambda^2$. In terms of the loop-induced effective $bs\gamma$ couplings $m_b \delta_\text{C}_{7L}^{R} + C_{7L}^{R} L_{\sigma\mu\nu} F_{\mu\nu} b$, it is $C_{7L}^{R}$ that receives larger contributions. This in itself provides some protection, since $C_{7L}^{R}$ is not generated in SM ($C_{7L}^{R \text{SM}} \approx -0.31$), hence our SUSY effects enter $b \to s\gamma$ rate only quadratically.

We find that, although RL mixing is suppressed by $m_b/\tilde{m}_1$, its effect dominates over the RR contribution for $\cos\sigma < 0$. Let us first show that $C_{7LR}^{R}$ is finite and suppressed by $m_0^2$ in the $\tilde{m}_1^2 \to 0$ limit. By direct computation, one finds that the $\tilde{s}_b\tilde{g}$ loop contribution to $m_b C_{7LR}^{R}$ is proportional to

$$\int dk^2 \frac{k^4}{(k^2 + m_0^2)^4} \left[ (\tilde{m}_1^2 - \tilde{m}_2^2) \right] \bigg|_{\tilde{m}_1^2 \to 0} \label{eq:5}$$

where “super-GIM” cancellation is ensured by Eq. (4), and the $\tilde{s}_b$ term decouples for heavy $m_0^2$. Since RR mixing is chiral conserving, a factor of $m_b$ is needed, while $m_0^2 c_{s\theta} e^{-i\sigma}$ is from $(\tilde{M}_{\ell LR}^{23,32})^2$.

FIG. 1. $b \to s\gamma$ vs CP phase $\sigma$ including both SM and SUSY effects, for $m_{\tilde{q}}$, $\tilde{m}_1 = 2$ TeV and several strange-beauty squark mass ($\tilde{m}_1 \equiv m_{\tilde{b}_s}$) values. The horizontal line indicates the SM expectation.
It is intriguing that, although $C_{\ell}^\gamma$ is subdominant compared to $C_{\ell}^{\gamma\gamma}$, its strength is actually not small. That is, $|C_{\ell}^\gamma|/C_{\ell}^{\gamma\gamma} \approx 0.35 - 0.12$ hence $\sin 2\theta = 2|C_{\ell}^\gamma|/(|C_{\ell}^\gamma|^2 + |C_{\ell}^{\gamma\gamma}|^2) \approx 63\% - 22\%$ for $\tilde{m}_1 = 100 - 1000$ GeV. New physics effects [14] such as mixing dependent CP violation in $b^0 \to K^0_{(1270)}\gamma$ could be of this order (though direct CP is small because $C_{\ell}^{\gamma\gamma}$ is small), but detectability may be better in $B_s \to \phi\gamma$. “Wrong” $\Lambda$-polarization in $\Lambda_b \to \Lambda\gamma$ could also be promising [14].

It is known that charged Higgs effects on $b \to s\gamma$ add constructively to the SM for all tan $\beta$ [13], giving rise to a very stringent constraint on $m_{H^\pm}$. Our light $s_{b_1}$ only worsens slightly the situation. Taking $2\sigma$ range of the measured $B \to X_s\gamma$ rate, we find $m_{H^\pm} > 620, 660$ (500, 600) GeV, respectively, for tan $\beta = 2, 60$ and $m_\phi = 0.8$ (1) TeV. The heaviess of $H^+$ implies that the second Higgs doublet is likely at the TeV scale as well.

Turning to charginos, as stated, the $\Delta m_K$ constraint demands that the wino part of chargino mass, controlled by $M_2$, should be larger than 500 GeV. Because of stringent bounds from $b \to s\gamma$, unless one makes fine-tuned cancellations [14] (e.g. with $H^+$ effect), the higgsino part of chargino mass, controlled by $\mu$, should also be at TeV scale, especially for large tan $\beta$. We do not entertain a light stop since we tacitly assume that flavor and SUSY scales are not too far apart [2], so the up squark mass average $\tilde{m}_u$ is also at $\tilde{m} \sim$ TeV. Thus, the charginos and the wino or higgsino-like neutralinos are all at TeV scale. This still leaves open the possibility of a light bino with mass controlled by $M_1$, which we call $\tilde{\chi}_1^0$. Interestingly, $b \to s\gamma$ is not very constraining here: we have taken the rather low mass value of $m_{\tilde{\chi}_1^0} = 90$ GeV in Fig. 1, and find that its effect is still much smaller than the dominant gluino contribution. This is simply because of the much weaker bino coupling (hypercharge) to down sector compared with the strong gluino couplings.

Without necessarily advocating a light bino, we thus have a scenario where SUSY particles and exotic Higgs bosons are at TeV scale, except for a possibly light neutralino $\tilde{\chi}_1^0$ that is largely bino, and a light strange-beauty squark $s_{b_1}$ with mass driven low by flavor violation!

One may worry that large $\tilde{q} - \tilde{s}_{b_1}$ (or $\tilde{\chi}_1^- - \tilde{\chi}_1^0$) splittings may violate $\delta R$ constraint. We first note that $\delta R$ picks up corrections to isovector gauge boson self-energy diagrams. Our light bino case is hence of no consequence. Because the isovector gauge interaction is left-handed, contributions from right handed squarks are transmitted through LR mixing [13]. However, this is suppressed in our case by $\tilde{M}_{LR}^2/\tilde{m}^2 \sim m_{s_{b_1}}/\tilde{m} \sim 10^{-4} - 10^{-3}$ [16], $\delta R$ can constrain only mass splittings in $\tilde{q}_L$, which are TeV scale particles and do not have large splittings, and thus the seemingly dangerous large splitting involving $s_{b_1}$ is safe from $\delta R$ constraint. We note in passing that our light $s_{b_1}$ can evade $R_b$ constraint also. The $\tilde{\chi}_1^- - d_{\gamma}$ contribution to $R_b$ is negligible [14] while $\chi^- - t$ gives sizable contribution only for light stop and light chargino, which is not the case in our model.

Large $s_{b-R}$ mixing, however, can easily impact on $B_s - B_s$ mixing and its CP phase $\Phi_{B_s}$, accessible soon at the Tevatron. Recall that $(\tilde{M}_s^2/\tilde{M}_R^2)/(\tilde{M}_s^2/\tilde{M}_R^2) \sim 1/\lambda \sim |V_{ts}/V_{td}|$ in Eq. (2), before setting $[\ldots]$ terms to zero. By simply scaling up the $B_d$ mixing results of [8] for $d_{b-R}$ mixing case, one sees that even for $\tilde{m}_1 \sim$ TeV, its contribution to $B_s$ mixing could be of same order as SM. The dominant $q-g$ box diagrams involve two $s_{b_1}$ or one $s_{b_1}$ and one $s_{\tilde{L}}/\tilde{b}_1$ with $s_{\tilde{L}}/\tilde{b}_1$ mixing. The former generates effective coupling $\propto \tilde{C}_1 s_{b-R}^\alpha b_R^\alpha b_R^\alpha b_R^\alpha$ while the latter $\propto C_{4(5)}^\alpha s_{b-R}^\alpha s_{\tilde{L}}^\beta s_{\tilde{L}}^\beta$, where $\tilde{C}_1 \propto c_d^2 s_b^2 e^{-2\sigma}$, $C_{4(5)} \propto \tilde{\chi}_1^0 s_d s_b e^{-i\sigma}$. Functions of $m_{\tilde{g}}^2/m_1^2$ (simpler mass insertion formulas given in [17]). Because of a larger loop factor, the CKM suppressed $C_{4(5)}$ is comparable to $\tilde{C}_1$. Thus, the explicit $\sigma$-phase dependence of the mixing amplitude is (a, b, c are real)

$$M_{12} \equiv |M_{12}| e^{2i\Phi_{B_s}} \approx a e^{-2i\sigma} + b e^{-i\sigma} + c,$$

where b (from $C_{4(5)}$) and c (from SM) differ in sign.

Using RGE evolution from [18] and $f_B^2/B = (240$ MeV)$^2$, we find $\Delta m_{B_s}^{SM} \simeq 14.9$ ps$^{-1}$ with vanishing $\sin 2\Phi_{B_s}$. For illustration, in Fig. 2 we plot $\Delta m_{B_s}$ and $\sin 2\Phi_{B_s}$ vs $\sigma$ for $\tilde{m}_1 = 1.2, 2, 3$ TeV, average squark mass $\tilde{m} = 2$ TeV and $m_\phi = 1, 2, 3$ TeV. As advertised, even for heavy $s_{b_1}$ at TeV scale, the SUSY contribution can be comparable to the SM effect. For $m_\phi = 1$ TeV $< \tilde{m}_1$, $\Delta m_{B_s}$ can reach twice the SM value around $\sigma = \pi$. For heavier $m_\phi$, $\Delta m_{B_s}$ can reach only 22 (18) ps$^{-1}$ for $m_\phi = 2 (3)$ TeV. Destructive interference between SM and SUSY for $\cos \sigma > 0$ (where $\cos \sigma$ modulation can be seen) would give $\Delta m_{B_s} < \Delta m_{B_s}^{SM}$ hence disfavored. Thus, for the $s_{b_1} \sim$ TeV scenario, $\cos \sigma < 0$ is preferred. Similarly, $|\sin 2\Phi_{B_s}|$ can reach 50% - 75%, vanishes at $\sigma = \pi$, and has smaller range for heavier $m_\phi$. If $\Delta m_{B_s}$ is only slightly above SM expectation, it could be uncovered at the Tevatron in a couple of years. One could then find $\sin 2\Phi_{B_s} \neq 0$ and indirect CP in $B_s \to \phi\gamma$, but no sign of SUSY particles since the scale is at TeV.

The light $s_{b_1}$ case allows greater range. We plot $\Delta m_{B_s}$ and $\sin 2\Phi_{B_s}$ vs $\sigma$ in Fig. 3, for $m_\phi = 0.8, 2, 3$ TeV, and $\tilde{m}_1 = 100, 200$ and 600 GeV. The $\tilde{m}_1 = 600$ GeV case
is similar to Fig. 2, except that \( a + b \) in Eq. (6) is of the same sign as \( c \). For lower \( \tilde{m}_1 \), the strength of \( b \) increases monotonically and is stronger than \( c \), while \( a \) first drops slowly, resulting in an accidental cancellation of \( \Delta m_{sB} \) at \( \sigma = 0 \) for \( \tilde{m}_1 \approx 200 \text{ GeV} \). Below this, \( a \) flips sign and changes rapidly, and together with \( b \) they overwhelm \( c \). Thus, for \( \tilde{m}_1 \lesssim 130 \text{ GeV} \), one develops a dip rather than maximum at \( \sigma \approx \pi \), as shown for \( \tilde{m}_1 = 100 \text{ GeV} \) case.

It is interesting that \( \Delta m_{sB} \) hovers not far above \( 15 \text{ ps}^{-1} \) for both a broad range of \( \tilde{m}_1 \gtrsim 250 \text{ GeV} \) and \( \cos \sigma > 0 \), and the intriguing case of a rather light (\( < 100 \text{ GeV} \) \( \tilde{s}_b \)) for phase \( \sigma \approx \pi \). For such \( \Delta m_{sB} \) values, measurement would be swift, with good prospects for sin \( 2\Phi_{B_s} \), which clearly covers the full range between \( \pm 1 \), with a sin \( 2\sigma \) modulation over the basic sin \( \sigma \) dependence. However, \( \Delta m_{sB} \) can also easily reach beyond \( 40 \text{ ps}^{-1} \), whether \( \tilde{s}_b \) is heavy or light, and measurement would then take a while. This in itself would indicate new physics, but sin \( 2\Phi_{B_s} \) measurement becomes difficult. For confirming evidence, one would have to search for \( C^\gamma \) effects in \( b \to s\gamma \), such as indirect \( CP \) in \( B_d \to K^\gamma_1 \) or “wrong” \( \Lambda \) polarization in \( \Lambda_b \to \Lambda \gamma \).

Whether \( \Delta m_{sB} \) (and sin \( 2\Phi_{B_s} \)) is measured soon or not, it is imperative to check whether there is a \( \tilde{s}_b \) squark below a couple hundred GeV. How should one search for it? In the usual SUSY scenario, because of heaviness of top quark, one could have a light stop by RGE evolution from very high scale, or by having large (flavor blind) LR mixing. One could also have a light sbottom if tan \( \beta \) is large. This has motivated the experimental search \[19\] via \( \tilde{b}_1 \to \tilde{b}_1 \tilde{\chi}_1^0 \) assuming that \( \tilde{\chi}_1^0 \), if not the lightest SUSY particle (LSP), is lighter than \( \tilde{b}_1 \). The signature is two b jets plus missing energy. In order to distinguish sbottom from stop, b-tagging is necessary since loop-induced \( \tilde{t}_1 \to c\tilde{\chi}_1^0 \) leads to similar signature. In our case, all squarks including stop are at TeV scale, except \( \tilde{s}_b \) which becomes light because of large flavor violation, without the need for large tan \( \beta \). Since \( \tilde{s}_b \) is a mixture of \( \tilde{s}_R \) and \( \tilde{b}_R \), both decays \( \tilde{s}_b \to b\chi_1^0 \), \( s\chi_1^0 \) are important, and the b-tagging efficiency is diluted. Thus, the standard sbottom search bound would weaken. In any case, if a light sbottom is found, one would have to check against production cross section vs theory expectations from mass measurement, to determine whether it is the standard \( \tilde{b}_1 \) or the \( \tilde{s}_b \). In case \( \chi_1^0 \) is heavier than \( \tilde{s}_b \), the LSP would likely be some sneutrino, and the decay \( \tilde{s}_b \to b\nu \), \( s\nu \) via virtual \( \chi_b^0 \) (hypercharge coupling) has similar signature.

In conclusion, flavor violation in \( s_R-b_R \) squark sector could be uniquely large if one has an underlying Abelian flavor symmetry, which are both inspired by the hierarchical patterns of quark masses and mixings. With SUSY above TeV scale, this large flavor violation could evade low energy constraints, including \( b \to s\gamma \), but modify \( B_s \) mixing and generate sin \( 2\Phi_{B_s} \neq 0 \). It is intriguing that the strange-beauty squark \( \tilde{s}_b \) could be driven light by the large flavor violation itself. Both a light \( \tilde{s}_b \) and a light bino-like neutralino \( \chi_1^0 \) can survive the \( b \to s\gamma \) constraint. This would not only further enrich \( B_s \) physics, but can also be directly probed via \( \tilde{s}_b \to b\chi_1^0, s\chi_1^0 \), which extends the standard \( b \to s\gamma \) search scenario.
