Abstract—A protograph-based low-density parity-check (LDPC) code design technique for bandwidth-efficient coded modulation is presented. The approach jointly optimizes the LDPC code node degrees and the mapping of the coded bits to the bit-interleaved coded modulation (BICM) bit-channels. For BICM with uniform input and for BICM with probabilistic shaping, binary-input symmetric-output surrogate channels are constructed and used for code design. The constructed codes perform as good as multi-edge type codes of Zhang and Kschischang (2013). For 64-ASK with probabilistic shaping, a blocklength 64800 code is constructed that operates within 0.69 dB of $\frac{1}{2}\log_2(1 + \text{SNR})$ at a spectral efficiency of 4.2 bits/channel use and a frame error rate of $10^{-3}$.

I. INTRODUCTION

Bit-interleaved coded modulation (BICM) combines high order modulation with binary error correcting codes [1]. This makes BICM attractive for practical application and BICM is widely used in standards, e.g., in DVB-T2/S2/C2. At a BICM receiver, bit-metric decoding (BMD) is used [2, Sec. III]. Achievable rates for BMD were investigated for uniformly distributed inputs in [2] and for non-uniformly distributed bits in [3]. These results were generalized to non-uniformly distributed input symbols in [4] and [5].

When designing low-density parity-check (LDPC) codes for BICM, the key challenge is to take into account the unequal error protection of the LDPC coded bits and the BICM bit-channels that are different for different bit-levels. A first approach is to take an existing LDPC code and to optimize the mapping of the coded bits to the BICM bit-levels. This was done, e.g., in [6]–[8]. A more fundamental approach is to directly incorporate the different bit-channels in the code design. This is done in [9], where the authors use multi-edge type (MET) codes [10] to parameterize the different bit-channels. They then extend the extrinsic information transfer charts (EXIT) [11] to multiple dimensions to design codes for quadrature amplitude modulation with 16 signal points (16-QAM). As 16-QAM can be constructed as the Cartesian product of two four point amplitude-shift keying (4-ASK) constellations, two different bit-channels are apparent. For constellations with more than two different bit-channels, the authors of [9] observe long runtimes of their multidimensional EXIT approach. Therefore, they suggest a high-order extension based on nesting, i.e., starting from $m = 2$, they successively extend their codes from $m$ to $m+1$ bit-levels by optimizing in each step only the additional bit-level.

In this work, we follow [9] and jointly optimize the code structure and the mapping of the coded bits to the BICM bit-levels. However, we propose a protograph-based design [12] and use protograph EXIT (PEXIT) analysis [13] to determine the ensemble iterative convergence threshold by accounting for the different bit-channels associated with the protograph variable nodes. The protograph ensemble is optimized with respect to the threshold by differential evolution. A design of protographs for coded modulation was first introduced in [14], which relies on a variable degree matched mapping (VDMM). More specifically, in [14] each bit-level is associated to a specific protograph variable node following the waterfilling approach (i.e., assigning the most protected coded bits to the bit-levels with highest bit-channel capacities). Recently, a protograph-based coded modulation scheme was introduced in [15] by performing a one-to-one mapping between the constellation symbols and the codeword symbols of a non-binary protograph LDPC code. This requires the constellation order to match the field order on which the LDPC code is constructed. To the best of our knowledge, none of the above-mentioned approaches leads to a joint binary LDPC protograph ensemble and bit-mapping optimization.

For the PEXIT analysis, we represent each bit-channel by a surrogate. Our surrogates reflect both the BICM bit-channels and the input distribution. We optimize codes both for uniformly distributed inputs and for the probabilistic shaping strategy proposed in [4]. Our optimized codes show a finite length performance that is as good as the one presented by Zhang and Kschischang [9]. Moreover, our design approach can be applied to very large constellations. For 64-ASK with probabilistic shaping, our blocklength 64800 code operates within 0.69 dB of $\frac{1}{2}\log_2(1 + \text{SNR})$ at a spectral efficiency of 4.2 bits/channel use and a frame error rate of $10^{-3}$.

This paper is organized as follows. In Sec. II, we review bit-metric decoding. We present our code design approach in Sec. III. In Sec. IV and Sec. V, we discuss the performance of our codes for uniform and shaped inputs, respectively.

II. BIT-METRIC DECODING

Consider the discrete time additive white Gaussian noise (AWGN) channel

$$Y = \Delta X + Z$$

(1)

where the noise term $Z$ is zero mean, unit variance Gaussian, and where the input $X$ is distributed on the normalized $2^m$-
uniformly distributed, then the ratio (SNR) is SNR $= 2$. 

**Remark 1.**

If the bits $B_1, B_2, \ldots, B_m$ are independent, then (5) can be written as [2], [3]

$$R_{BMD} = \sum_{i=1}^{m} I(B_i; L_i)$$

where $I(\cdot; \cdot)$ denotes mutual information.

**Remark 2.**

If the bits $B_1, B_2, \ldots, B_m$ are independent and uniformly distributed, then the $L$-values (3) can be written as

$$L_i = \log \frac{P_{Y|(B_1\ldots B_m)}(y|0)}{P_{Y|(B_1\ldots B_m)}(y|1)}.$$
where the \( \tilde{\sigma} \) done by PEXIT analysis [13]. For EXIT chart analysis, the C. PEXIT Analysis 

We use biAWGN channels with uniform input as surrogate the individual conditional entropies in (15) for each bit-level. Since we want to account for the different bit-channels, we restrict our surrogate channel further by requiring equality for the achievable information values \( I_E \) per \((V_k,C_i)\) pair to accommodate for the edge connections imposed by the protograph basematrices and the (possibly different) reliability of the coded bits \( V_k \). The PEXIT algorithm is summarized as follows:

1. Initialize each \( \sigma_{ch}, k \in \{1, \ldots, f\} \) with a corresponding \( \sigma_{B_i}, i \in \{1, \ldots, m\} \) (17) originating from the biAWGNC surrogates. For all tuples \((V_k,C_i), k \in \{1, \ldots, f\}, f \in \{1, \ldots, c\} \), set the a priori mutual information values \( I_{E_{V_k \rightarrow V_k}} = 0 \).
2. Perform variable to check node update (8) for all tuples \((V_k,C_i)\).
3. Perform check to variable node update (9) for all tuples \((V_k,C_i)\).
4. Calculate \( I_{\text{APP}_k}, k \in \{1, \ldots, f\} \) (10).
5. Stop if all \( I_{\text{APP}_k} = 1 \), otherwise go to 2.

IV. CODE DESIGN FOR UNIFORM INPUTS

A. Optimization Procedure for Protograph Ensembles

We impose restrictions on the dimension of the basematrix \( A \in \{0,1, \ldots, S\}^{e \times f} \). The parameters \( e \) and \( f \) determine how many different variable degrees per bit-channel can occur and are chosen to represent the desired code rate \( c = \frac{L-\epsilon}{L} \). The maximum number of parallel edges \( S \) is crucial for both the performance of the code and the success of the optimization procedure. The product \( e \cdot S \) describes the maximum variable node degree in the final code and thereby determines the size of the optimization search space. The optimization of the basemats is performed by differential evolution (DE), see [18].

B. Numerical Results

In order to compare our code design approach to the setting of Zhang and Kschischang [9], we design codes of rates 1/2 and 3/4 for 4-ASK constellations with uniform inputs. The optimized protographs are depicted in Table 4. We discuss the rate 1/2 code in more detail. The coded bits are transmitted over two different bit-channels. For each bit-channel, we allow 3 (possibly different) variable degrees so that always 3 variable nodes in the protograph are assigned to the same surrogate channel: \( \sigma_{ch}^2 = \sigma_{ch}^2 = \sigma_{ch}^2 = 4/\sigma_{B_2}^2 \), \( \sigma_{ch}^2 = \sigma_{ch}^2 = \sigma_{ch}^2 = \sigma_{ch}^2 = 4/\sigma_{B_3}^2 \). Once the optimized basematrices have been found, we construct quasi-cyclic parity-check matrices with blocklengths \( n = 16200 \). We simulate the constructed codes

\[
I_{E_{V_k \rightarrow C_i}} = J \left( \sum_{l'=1}^{c} b_{l'}^k \cdot J^{-1} \left( I_{E_{C_i \rightarrow V_k}} \right)^2 + (b_{l'} - 1) \cdot J^{-1} \left( I_{E_{C_i \rightarrow V_k}} \right)^2 + \sigma_{ch}^2 \right) \tag{8}
\]

\[
I_{E_{C_i \rightarrow V_k}} = 1 - J \left( \sum_{l'=1}^{f} b_{l'}^k \cdot J^{-1} \left( 1 - I_{E_{V_k \rightarrow C_i}} \right)^2 + (b_{l'} - 1) \cdot J^{-1} \left( 1 - I_{E_{V_k \rightarrow C_i}} \right)^2 \right) \tag{9}
\]

\[
I_{\text{APP}_k} = J \left( \sum_{l'=1}^{f} b_{l'}^k \cdot J^{-1} \left( I_{E_{C_i \rightarrow V_k}} \right)^2 + \sigma_{ch}^2 \right). \tag{10}
\]
using 100 decoding iterations. The bit error rates (BER) and frame error rates (FER) in Fig. 5 and 6 show that the finite length performance of our codes is equal to or slightly better than the codes in [9]. The decoding thresholds given in Table 4 are obtained by PEXIT analysis for the surrogate channels.

V. CODE DESIGN FOR SHAPED INPUTS

We briefly outline how our design procedure can be used to design LDPC codes for the probabilistic shaping scheme proposed in [4].

A. Probabilistic Shaping

Fig. 7 illustrates the shaping scheme. The key observation is that the capacity-achieving distribution of ASK constellations in Gaussian noise is symmetric around the origin. Consequently, the capacity-achieving distribution induces a distribution \( P_{B_2 \cdots B_m} \) on the BRGC labeling with the following properties:

- bit-level \( B_1 \) is uniformly distributed (bit-level \( B_1 \) decides on the sign of the transmitted constellation point, see Fig. 1).
- bit-levels \( B_2 \cdots B_m \) and bit-level \( B_1 \) are independent. bit-levels \( B_2 \cdots B_m \) are correlated.

This suggests to mimic the capacity-achieving distribution in the following way: first, generate bit-levels \( B_2 \cdots B_m \) according to \( P_{B_2 \cdots B_m} \), e.g., by using a distribution matcher (see Fig. 7). Then encode by a systematic encoder of rate \( 1/m \), e.g., by using a distribution matcher. The decoder appends check bits \( B_1 \) that are approximately uniformly distributed because each check bit is a modulo two sum of many information bits [19, Sec. 7.1]. The signal point \( x_{B_1 B_2 \cdots B_m} \) selected by the bit-mapper then has approximately the capacity-achieving distribution.

B. Surrogate Channels

As discussed before, the channel appears to the receiver as a set of \( m \) parallel binary input channels, see Fig. 2. The non-uniform distribution \( P_{B_2 \cdots B_m} \) influences each channel law \( P_{L_i | B_1} \) via (4). Consequently, it also influences the conditional entropies \( H(B_1 | L_i) \) in our surrogate channels (17) that we use for code optimization.
C. Numerical Results

We optimize codes for 64-ASK with probabilistic shaping. To obtain a close-to-optimal input distribution, we use the approach of [20, 5, Sec. 3] with a sampled Gaussian (Maxwell-Boltzmann) distribution. We maximize the resulting BMD rate (5) over the constellation spacing \( \Delta \) in (1). The results are shown in Fig. 8. Our optimized protograph code of blocklength \( n = 64800 \) shows a gap of 0.69 dB to AWGN capacity at 4.2 bits/channel use for FER = \( 10^{-3} \). Our operating point is 0.66 dB more energy efficient than ideal uniform 64-ASK and 1.17 dB more energy efficient than ideal uniform 64-ASK with bit-metric decoding.

VI. CONCLUSION

We proposed a protograph-based LDPC code design approach for bandwidth-efficient coded modulation that is suitable both for uniform and shaped inputs. The different bit-channels are replaced by biAWGN surrogates so that PEXIT and differential evolution give ensembles with good decoding thresholds. The performance of the new codes for uniform inputs are as good as the best codes in literature. For shaped inputs, the new codes operate close to \( \frac{1}{2} \log_2 (1 + \text{SNR}) \). Future research should investigate the influence of the surrogates on the code performance by employing a full-fledged density evolution for protographs. Furthermore, precoded protographs should be considered to improve the threshold without increasing the variable node degrees.
