ABSTRACT. In 2005 Li et al. gave a $\varphi$-competitive deterministic online algorithm for scheduling of packets with agreeable deadlines [12] with a very interesting analysis. This is known to be optimal due to a lower bound by Hajek [7]. We claim that the algorithm by Li et al. can be slightly simplified, while retaining its competitive ratio. Then we introduce randomness to the modified algorithm and argue that the competitive ratio against oblivious adversary is at most $\frac{4}{3}$. Note that this still leaves a gap between the best known lower bound of $\frac{5}{4}$ by Chin et al. [5] for randomized algorithms against oblivious adversary.

1. Introduction

We consider the problem of buffer management with bounded delay (aka packet scheduling), introduced by Kesselman et al. [11]. It models the behaviour of a single network switch. We assume that time is slotted and divided into steps. At the beginning of a time step, any number of packets may arrive at a switch and are stored in its buffer. A packet has a positive weight and a deadline, which is the number of step right before which the packet expires: unless it has already been transmitted, it is removed from the buffer at the very beginning of that step and thus can no longer be transmitted. Only one packet can be transmitted in a single step. The goal is to maximize the weighted throughput, i.e., the total weight of transmitted packets.

As the process of managing packet queue is inherently a real-time task, we investigate the online variant of the problem. This means that the algorithm has to base its decision of which packet to transmit solely on the packets which have already arrived at a switch, without the knowledge of the future.
1.1. Competitive Analysis.

To measure the performance of an online algorithm, we use a standard notion of competitive analysis [3], which compares the gain of the algorithm to the gain of the optimal solution on the same input sequence. For any algorithm \(\text{Alg}\), we denote its gain on the input sequence \(I\) by \(G_{\text{ALG}}(I)\); we denote the optimal offline algorithm by \(\text{Opt}\). We say that a deterministic algorithm \(\text{Alg}\) is \(R\)-competitive if on any input sequence \(I\), it holds that \(G_{\text{ALG}}(I) \geq \frac{1}{R} \cdot G_{\text{OPT}}(I)\).

When analysing the performance of an online algorithm \(\text{Alg}\), we view the process as a game between \(\text{Alg}\) and an adversary. The adversary controls the packets’ injection into the buffer and chooses which of them to send. The goal is then to show that the adversary’s gain is at most \(R\) times \(\text{Alg}\)’s gain.

If the algorithm is randomized, we consider its expected gain, \(\mathbb{E}[G_{\text{ALG}}(I)]\), where the expectation is taken over all possible random choices made by \(\text{Alg}\). However, in the randomized case, the power of the adversary has to be further specified. Following Ben-David et al. [1], we distinguish between an oblivious and adaptive-online adversary (called adaptive for short). An oblivious adversary has to construct the whole input sequence in advance, not knowing the random bits used by an algorithm. The expected gain of \(\text{Alg}\) is compared to the gain of the optimal offline solution on \(I\). An adaptive adversary decides packet injections upon seeing which packets are transmitted by the algorithm. However, it has to provide an answering entity \(\text{Adv}\), which creates a solution on-line (in parallel to \(\text{Alg}\)) and cannot change it afterwards. We say that \(\text{Alg}\) is \(R\)-competitive against an adaptive adversary if for any input sequence \(I\) created adaptively and any answering algorithm \(\text{Adv}\), it holds that \(\mathbb{E}[G_{\text{ALG}}(I)] \geq \frac{1}{R} \cdot \mathbb{E}[G_{\text{ADV}}(I)]\). We note that \(\text{Adv}\) is (wlog) deterministic, but as \(\text{Alg}\) is randomized, so is the input sequence \(I\).

In the literature on online algorithms (see e.g. [3]), the definition of the competitive ratio sometimes allows an additive constant, i.e., a deterministic algorithm is \(R\)-competitive if there exists a constant \(\alpha \geq 0\) such that \(G_{\text{ALG}}(I) \geq \frac{1}{R} \cdot G_{\text{OPT}}(I) - \alpha\) holds for every input sequence \(I\). An analogous definition applies to randomized case. Our upper bounds hold for \(\alpha = 0\).

1.2. Previous work

The best known deterministic and randomized algorithms for general instances have competitive ratios at most \(2\sqrt{2} - 1 \approx 1.828\) [6] and \(e/(e - 1) \approx 1.582\) [4], respectively. A recent analysis of the latter algorithm shows that it retains its competitive ratio even against adaptive-online adversary [8].

The best known lower bounds on competitive ratio against either adversary type use rather restricted 2-bounded sequences in which every packet has lifespan (deadline – release time) either 1 or 2. The lower bounds in question are \(\phi \approx 1.618\) for deterministic algorithms [7], \(\frac{4}{3}\) for randomized algorithms against adaptive adversary [2], and \(\frac{5}{4}\) for randomized algorithms against oblivious adversary [5]. All these bounds are tight for 2-bounded sequences [11, 2, 4].

We restrict ourselves to sequences with agreeable deadlines, in which packets released later have deadlines at least as large as those released before \((r_i < r_j \text{ implies } d_i \leq d_j)\). These strictly generalize the 2-bounded sequences. Sequences with agreeable deadlines also properly contain \(s\)-uniform sequences for all \(s\), i.e., sequences in which every packet has
lifespan exactly \( s \). An optimal \( \phi \)-competitive deterministic algorithm for sequences with agreeable deadlines is known [12].

Ježabek studied the impact of resource augmentation on the deterministic competitive ratio [10, 9]. It turns out that while allowing the deterministic algorithm to transmit \( k \) packets in a single step for any constant \( k \) cannot make it 1-competitive (compared to the single-speed offline optimum) on unrestricted sequences [10], \( k = 2 \) is sufficient for sequences with agreeable deadlines [9].

### 1.3. Our contribution

Motivated by aforementioned results for sequences with agreeable deadlines, we investigate randomized algorithms for such instances. We devise a \( \frac{4}{3} \)-competitive randomized algorithm against oblivious adversary. The algorithm and its analysis are inspired by those by Li et al. [12] for deterministic case. The key insight is as follows. The algorithm MG by Li et al. [12] can be simplified by making it always send either \( e \), the heaviest among the earliest non-dominated packets, or \( h \), the earliest among the heaviest non-dominated packets. We call this algorithm MG', and prove that it remains \( \phi \)-competitive. Then we turn it into a randomized algorithm RG, simply by making it always transmit \( e \) with probability \( \frac{w_i}{w_h} \) and \( h \) with the remaining probability. The proof of RG's \( \frac{4}{3} \)-competitiveness against oblivious adversary follows by similar analysis.

### 2. Preliminaries

We denote the release time, weight, and deadline of a packet \( j \) by \( r_j \), \( w_j \), and \( d_j \), respectively. A packet \( j \) is pending at step \( t \) if \( r_j \leq t \), it has not yet been transmitted, and \( d_j > t \). We introduce a linear order \( \preceq \) on the packets as follows: \( i \preceq j \) if either

\[
\begin{align*}
  &d_i < d_j, \\
  &d_i = d_j \text{ and } w_i > w_j, \\
  &d_i = d_j \text{ and } w_i = w_j \text{ and } r_i \leq r_j .
\end{align*}
\]

To make \( \preceq \) truly linear we assume that in every single step the packets are released one after another rather than all at once, e.g. that they have unique fractional release times.

A schedule is a mapping from time steps to packets to be transmitted in those time steps. A schedule is feasible if it is injective and for every time step \( t \) the packet that \( t \) maps to is pending at \( t \). It is convenient to view a feasible schedule \( S \) differently, for example as the set \( \{ S(t) : t > 0 \} \), the sequence \( S(1), S(2), \ldots \), or a matching in the schedulability graph. The schedulability graph is a bipartite graph, one of whose partition classes is the set of packets and the other is the set of time steps. Each packet \( j \) is connected precisely to each of the time steps \( t \) such that \( r_j \leq t < d_j \) by an edge of weight \( w_j \); an example is given in Figure 1. Observe that optimal offline schedules correspond to maximum weight matchings in the schedulability graph. Thus an optimal offline schedule can be found in polynomial time using the classic "Hungarian algorithm", see for example [13]. One may have to remove appropriately chosen time step vertices first, so that the remaining ones match the number of packet vertices, though.

Given any linear order \( \preceq \) on packets and a (feasible) schedule \( S \), we say that \( S \) is consistent with \( \preceq \), or that \( S \) is a \( \preceq \)-schedule, if for every \( t \) the packet \( S(t) \) is the minimum pending packet with respect to \( \preceq \). It is fairly easy to observe that if \( \preceq \) is any earliest deadline
first, with ties broken in an arbitrary way, then any feasible schedule can be turned to a unique \(\preceq\)-schedule by reordering its packets; in particular this applies to \(\preceq\).

Recall that the oblivious adversary prepares the whole input sequence in advance and cannot alter it later on. Thus its solution is simply the offline optimal schedule for the complete sequence. Nevertheless, we still refer to the answering entity \(\text{ADV}\) rather than \(\text{OPT}\) in our analysis, as it involves altering the set of packets pending for the adversary, which may well be viewed as altering the input sequence. Now we introduce two schedules that are crucial for our algorithms and our analyzes.

**Definition 2.1.** The oblivious schedule at time step \(t\), denoted \(O_t\), is any fixed optimal feasible \(\preceq\)-schedule over all the packets pending at step \(t\). For fixed \(O_t\), a packet \(j\) pending at \(t\) is called dominated if \(j \not\in O_t\), and non-dominated otherwise. For fixed \(O_t\) let \(e\) denote \(O_t(t)\), the \(\preceq\)-minimal of all non-dominated packets, and \(h\) denote the \(\preceq\)-minimal of all non-dominated maximum-weight packets.

Note that both the adversary and the algorithm can calculate their oblivious schedules at any step, and that these will coincide if their buffers are the same.

**Definition 2.2.** For a fixed input sequence, the clairvoyant schedule at time step \(t\), denoted \(C_t\), is any fixed optimal feasible schedule over all the packets pending at step \(t\) and all the packets that will arrive in the future.

Naturally, the adversary can calculate the clairvoyant schedule, as it knows the fixed input sequence, while the algorithm cannot, since it only knows the part of input revealed so far. However, the oblivious schedule gives some partial information about the clairvoyant schedule: intuitively, if \(p\) is dominated at \(t\), it makes no sense to transmit it at \(t\). Formally, (wlog) dominated packets are not included in the clairvoyant schedule, as stated in the following.

**Fact 2.3.** For any fixed input sequence, time step \(t\), and oblivious schedule \(O_t\), there is a clairvoyant schedule \(C_t^*\) such that \(C_t^* \cap \{j : r_j \leq t\} \subseteq O_t\).

**Proof.** This is a standard alternating path argument about matchings. If you are unfamiliar with these concepts, refer to a book by A. Schrijver [13] for example.

Let \(O_t\) be the oblivious schedule and \(C_t\) be any clairvoyant schedule. Treat both as matchings in the schedulability graph and consider their symmetric difference \(C_t \oplus O_t\).
Consider any job \( j \in C_t \setminus O_t \) such that \( r_j \leq t \). It is an endpoint of an alternating path \( P \) in \( C_t \oplus O_t \). Note that all the jobs on \( P \) are already pending at time \( t \): this is certainly true about \( j \), and all the successive jobs belong to \( O_t \), so they are pending as well.

First we prove that \( P \) has even length, i.e., it ends in a node corresponding to a job. Assume for contradiction that \( P \)'s length is odd, and that \( P \) ends in a node corresponding to a timestep \( t' \). Note that no job is assigned to \( t' \) in \( O_t \). Then \( O_t \oplus P \) is a feasible schedule that, treated as a set, satisfies \( O_t \subseteq O_t \oplus P \) and \( j \in O_t \oplus P \). This contradicts optimality of \( O_t \). See Figure 2a for illustration.

Thus \( P \) has even length and ends with a job \( j' \in O_t \setminus C_t \). By optimality of both \( O_t \) and \( C_t \), \( w_j = w_{j'} \) holds. Thus \( C_t \oplus P \) is an optimal feasible schedule: in terms of sets the only difference between \( C_t \) and \( C_t \oplus P \) is that \( j \) has been replaced by \( j' \), a job of the same weight. See Figure 2b for illustration.

Figure 2: The alternating path \( P \). Packets are represented by discs, time steps by squares. Dashed lines represent \( C_t \), solid lines represent \( O_t \).

Applying such changes iteratively transforms \( C_t \) to a clairvoyant schedule \( C_t^* \) as announced. To observe that a finite number of iterations suffices, define \( \Delta(S) := |S \cap \{ j : r_j \leq t \} \setminus O_t| \) for any schedule \( S \). It follows that \( \Delta(C_t \oplus P) = \Delta(C_t) - 1 \). Since \( \Delta \) is non-negative and its value drops by one with each iteration, \( C_t^* \) is obtained in a finite number of steps.

**Definition 2.4.** We say that a clairvoyant schedule \( C_t^* \) conforms with an oblivious schedule \( O_t \) if \( C_t^* \) is a \( \preceq \)-schedule, \( C_t \cap \{ j : r_j \leq t \} \subseteq O_t \), and for all \( i \in O_t \) such that \( i \preceq j = C_t(t) \), \( w_i < w_j \) holds.

**Fact 2.5.** For every oblivious schedule \( O_t \) there is a conforming clairvoyant schedule \( C_t^* \).

**Proof.** Let \( C_t \) be a clairvoyant schedule such that \( C_t \cap \{ j : r_j \leq t \} \subseteq O_t \); Fact 2.3 guarantees its existence. Let \( C_t' \) be the schedule obtained from \( C_t \) by first turning it into a \( \preceq \)-schedule \( C_t' \) and then replacing \( j = C_t'(t) \) with a \( \preceq \)-minimal non-dominated packet \( j' \) of the same weight.

If \( j' = j \), then \( C_t^* = C_t' \), and thus it is a clairvoyant \( \preceq \)-schedule. Assume \( j' \neq j \), i.e., \( j' \prec j \). Then \( j' \notin C_t' \), since \( C_t' \) is a \( \preceq \)-schedule. Thus \( C_t^* \) is feasible as we replace \( C_t' \)'s very first packet by another pending packet which was not included in \( C_t \). Observe that \( C_t^* \) is indeed a clairvoyant \( \preceq \)-schedule: optimality follows from \( w_{j'} = w_j \), while consistency with \( \preceq \) follows from \( j' \prec j \).
It remains to prove that for every $i \in O_t$ such that $i < j'$, $w_i < w_{j'} = w_j$ holds. Note that $i \notin C_t^*$ as $C_t^*$ is a $\leq$-schedule, and that $w_i \neq w_{j'} = w_j$ holds by the choice of $j'$. Assume for contradiction that $w_i > w_j$. Then $C_t^*$ with $j$ replaced by $i$ is a feasible schedule contradicting optimality of $C_t^*$.

Now we inspect some properties of conforming schedules.

**Fact 2.6.** Let $C_t$ be a clairvoyant schedule conforming with an oblivious schedule $O_t$. If $i, j \in O_t$, $w_i < w_j$ and $d_i < d_j$ (or, equivalently $w_i < w_j$ and $i < j$), and $i \in C_t$, then also $j \in C_t$.

**Proof.** Assume for contradiction that $j \notin C_t$. Then $C_t$ with $i$ replaced by $j$ is a feasible schedule contradicting optimality of $C_t$.

**Lemma 2.7.** Let $C_t$ be a clairvoyant schedule conforming with an oblivious schedule $O_t$. Suppose that $e = O_t(t) \notin C_t$. Then there is a clairvoyant schedule $C_t^*$ obtained from $C_t$ by reordering of packets such that $C_t^*(t) = h$.

**Proof.** Let $j = C_t(t) \neq h$ and let $O_t = p_1, p_2, \ldots, p_s$. Observe that $h \in C_t$ by Fact 2.6. So in particular $e = p_1$, $j = p_k$, and $h = p_l$ for some $1 < k < l \leq s$. Let $d_i$ denote the deadline of $p_i$ for $1 \leq i \leq s$. Since $O_t$ is feasible in the absence of future arrivals, $d_i \geq t + i$ for $i = 1, \ldots, s$.

Recall that $p_k, p_l \in C_t$ and that there can be some further packets $p \in C_t$ such that $p_k < p < p_l$; some of these packets may be not pending yet. We construct a schedule $C_t'$ by reordering $C_t$. Precisely, we put all the packets from $C_t$ that are not yet pending at $t$ after all the packets from $C_t$ that are already pending, keeping the order between the pending packets and between those not yet pending. By the agreeable deadlines property, this is an earliest deadline first order, so $C_t'$ is a clairvoyant schedule.

As $e = p_1 \notin C_t'$ and $d_i \geq t + i$ for $i = 1, \ldots, s$, all the packets $x \in C_t'$ preceding $h$ in $C_t'$ (i.e., $x \in C_t'$ such that $r_x \leq t$ and $x < p_l = h$) have slack in $C_t'$, i.e., each of them could also be scheduled one step later. Hence $h = p_l$ can be moved to the very front of $C_t'$ while keeping its feasibility, i.e., $C_t' = p_k, p_k', \ldots, p_l, p_l$ can be transformed to a clairvoyant schedule $C_t^* = p_l, p_k, p_k', \ldots, p_l$. The reordering is illustrated in Figure 3.

![Figure 3: Construction of the schedule $C_t^*$. Packets are represented by circles: the ones included in $C_t$ ($C_t^*$) are filled, the remaining ones are hollow.](image)

3. Algorithms and their analyzes

3.1. The Algorithms

The algorithm MG [12] works as follows: at the beginning of each step $t$ it considers the packets in the buffer and the newly arrived packets, and calculates $O_t$. Then MG identifies the packets $e$ and $h$. If $\phi w_e \geq w_h$, MG sends $e$. Otherwise, it sends the $\leq$-minimal packet $f$ such that $w_f \geq \phi w_e$ and $\phi w_f \geq w_h$; the latter exists as $h$ itself is a valid candidate. Our deterministic algorithm MG’ does exactly the same with one exception: if $\phi w_e < w_h$, it sends $h$ rather than $f$. Our randomized algorithm RG also works in a similar fashion: it transmits $e$ with probability $\frac{w_e}{w_h}$ and $h$ with the remaining probability. For completeness, we provide pseudo-codes of all three algorithms in Figure 4.

MG (step $t$)

$O_t \leftarrow$ oblivious schedule at $t$
$e \leftarrow$ the $\leq$-minimal packet from $O_t$
$h \leftarrow$ the $\leq$-minimal of all the heaviest packets from $O_t$

if $\phi w_e \geq w_h$
then transmit $e$
else $f \leftarrow$ the $\leq$-minimal of all $j \in O_t$ s.t. $w_j \geq \phi w_e$ and $\phi w_j \geq w_h$
transmit $f$

MG’ (step $t$)

$O_t \leftarrow$ oblivious schedule at $t$
$e \leftarrow$ the $\leq$-minimal packet from $O_t$
$h \leftarrow$ the $\leq$-minimal of all the heaviest packets from $O_t$

if $\phi w_e \geq w_h$
then transmit $e$
else transmit $h$

RG (step $t$)

$O_t \leftarrow$ oblivious schedule at $t$
$e \leftarrow$ the $\leq$-minimal packet from $O_t$
$h \leftarrow$ the $\leq$-minimal of all the heaviest packets from $O_t$
transmit $e$ with probability $\frac{w_e}{w_h}$ and $h$ with probability $1 - \frac{w_e}{w_h}$

Figure 4: The three algorithms

3.2. Analysis Idea

The analysis of Li et al. [12] uses the following idea: in each step, after both MG and Adv transmitted their packets, modify Adv’s buffer in such a way that it remains the same as MG’s and that this change can only improve Adv’s gain, both in this step and in the future. Sometimes Adv’s schedule is also modified to achieve this goal, specifically, the packets in it may be reordered, and Adv may sometimes be allowed to transmit two packets in a single step. It is proved that in each such step the ratio of Adv’s to MG’s gain
is at most $\phi$. As was already noticed by Li et al. [12], this is essentially a potential function argument. To simplify the analysis, it is assumed (wlog) that $\text{Adv}$ transmits its packets in the $\preceq$ order.

Our analysis follows the outline of the one by Li et al., but we make it more formal. Observe that there may be multiple clairvoyant schedules, and that $\text{Adv}$ can transmit $C_t(t)$ at every step $t$, where $C_t$ is a clairvoyant schedule chosen arbitrarily in step $t$. As our algorithms $\text{MG}'$ and $\text{RG}$ determine the oblivious schedule $O_t$ at each step, we assume that every $C_t$ is a clairvoyant schedule conforming with $O_t$.

There is one exception though. Sometimes, when a reordering in $C_t$ does not hinder $\text{Adv}$’s performance (taking future arrivals into account), we “force” $\text{Adv}$ to follow the reordered schedule. This is the situation described in Lemma 2.7: when $e \notin C_t$, there is a clairvoyant schedule $C_t^*$ such that $h = C_t^*(t)$. In such case we may assume that $\text{Adv}$ follows $C_t^*$ rather than $C_t$, i.e., that it transmits $h$ at $t$. Indeed, we make that assumption whenever our algorithm (either $\text{MG}'$ or $\text{RG}$) transmits $h$ at such step: then $\text{Adv}$ and $\text{MG}'$ ($\text{RG}$) transmit the same packet, which greatly simplifies the analysis.

Our analysis of $\text{MG}'$ is essentially the same as the original analysis of $\text{MG}$ by Li et al. [12], but lacks one case which is superfluous due to our modification. As our algorithm $\text{MG}'$ always transmits either $e$ or $h$, and the packet $j$ that $\text{Adv}$ transmits always satisfies $j \preceq h$ by definition of the clairvoyant schedule conforming with $O_t$, the case which $\text{MG}$ transmits $f$ such that $e \prec f \prec j$ does not occur to $\text{MG}'$. The same observation applies to $\text{RG}$, whose analysis also follows the ideas of Li et al.

### 3.3. Analysis of the Deterministic Algorithm

We analyze this algorithm as mentioned before, i.e., assuming (wlog) that at every step $t$ $\text{Adv}$ transmits $C_t(t)$, where $C_t$ is a clairvoyant schedule conforming with $O_t$.

**Theorem 3.1.** $\text{MG}'$ is $\phi$-competitive on sequences with agreeable deadlines.

**Proof.** Note that whenever $\text{MG}'$ and $\text{Adv}$ transmit the same packet, clearly their gains are the same, as are their buffers right after such step. In particular this happens when $e = h$ as then $\text{MG}'$ transmits $e = h$ and $\text{Adv}$ does the same: in such case $h$ is both the heaviest packet and the $\preceq$-minimal non-dominated packet, so $h = C_t(t)$ by definition of the clairvoyant schedule conforming with $O_t$.

In what follows we inspect the three remaining cases.

$
\phi w_e \geq w_h$: $\text{MG}'$ transmits $e$. $\text{Adv}$ transmits $j \neq e$. To make the buffers of $\text{MG}'$ and $\text{Adv}$ identical right after this step, we replace $e$ in $\text{Adv}$’s buffer by $j$. This is advantageous for $\text{Adv}$ as $d_j \geq d_e$ and $w_j \geq w_e$ follows from $e \preceq j$ and the definition of a clairvoyant schedule conforming with $O_t$. As $\phi w_e \geq w_h$, the ratio of gains is 

$$
\frac{w_j}{w_e} \leq \frac{w_h}{w_e} \leq \phi .
$$
\[ \phi w_e < w_h : \] MG' transmits \( h \). ADV transmits \( e \). Note that ADV’s clairvoyant schedule from this step contains \( h \) by Fact 2.6. We let ADV transmit both \( e \) and \( h \) in this step and keep \( e \) in its buffer, making it identical to the buffer of MG'. Keeping \( e \), as well as transmitting two packets at a time is clearly advantageous for ADV. As \( \phi w_e < w_h \), the ratio of gains is

\[
\frac{w_e + w_h}{w_h} \leq \frac{1}{\phi} + 1 = \phi .
\]

\[ \phi w_e < w_h : \] MG' transmits \( h \). ADV transmits \( j \neq e \). Note that \( j \subseteq h \): by definition of the clairvoyant schedule conforming with \( O_t \), for every \( i \in O_t \) such that \( i < j \), \( w_i < w_j \) holds.

There are two cases: either \( j = h \), or \( w_j < w_h \) and \( d_j < d_h \). In the former one both players do the same and end up with identical buffers. Thus we focus on the latter case. Fact 2.6 implies that \( h \in C_t \). By Lemma 2.7, \( C_t \) remains feasible when \( h \) is moved to its very beginning. Hence we assume that ADV transmits \( h \) in the current step. As this is the packet that MG' sends, the gains of ADV and MG' are the same and no changes need be made to ADV's buffer.

3.4. Analysis of the Randomized Algorithm

We analyze this algorithm as mentioned before, i.e., assuming (wlog) that at every step \( t \) ADV transmits \( C_t(t) \), where \( C_t \) is a clairvoyant schedule conforming with \( O_t \).

Theorem 3.2. RG is \( 4/3 \)-competitive against oblivious adversary on sequences with agreeable deadlines.

Proof. Observe that if \( e = h \), then RG transmits \( e = h \) and ADV does the same: as in such case \( h \) is both the heaviest packet and the \( \leq \)-minimal non-dominated packet, \( h = C_t(t) \) by definition of the clairvoyant schedule conforming with \( O_t \). In such case the gains of RG and ADV are clearly the same, as are their buffers right after step \( t \). Thus we assume \( e \neq h \) from now on.

Let us first bound the algorithm’s expected gain in one step. It equals

\[
G_{\text{RG}} = \frac{w_e}{w_h} \cdot w_e + \left( 1 - \frac{w_e}{w_h} \right) \cdot w_h \\
= \frac{1}{w_h} \left( w_e^2 - w_e w_h + w_h^2 \right) \\
= \frac{1}{w_h} \left( \left( w_e - \frac{w_h}{2} \right)^2 + \frac{3}{4} w_h^2 \right) \\
\geq \frac{3}{4} w_h .
\]

Now we describe the changes to ADV’s scheduling policy and buffer in the given step. These make ADV’s RG’s buffers identical, and, furthermore, make the expected gain of the adversary equal exactly \( w_h \). This, together with (3.1) yields the desired bound. To this end we consider cases depending on ADV’s choice.
(1) ADV transmits $e$. Note that ADV’s clairvoyant schedule from this step contains $h$ by Fact 2.6.

If RG transmits $e$, which it does with probability $\frac{w_e}{w_h}$, both players gain $w_e$ and no changes are required.

Otherwise RG transmits $h$, and we let ADV transmit both $e$ and $h$ in this step and keep $e$ in its buffer, making it identical to RG’s buffer. Keeping $e$, as well as transmitting two packets at a time is clearly advantageous for ADV.

Thus in this case the adversary’s expected gain is

$$G_{ADV} = \frac{w_e}{w_h} \cdot w_e + \left(1 - \frac{w_e}{w_h}\right)(w_e + w_h) = w_e + (w_h - w_e) = w_h.$$  

(2) ADV transmits $j \neq e$. Note that $j \leq h$: by definition of the clairvoyant schedule conforming with $O_t$, for every $i \in O_t$ such that $i < j$, $w_i < w_j$ holds.

If RG sends $e$, which it does with probability $\frac{w_e}{w_h}$, we simply replace $e$ in ADV’s buffer by $j$. This is advantageous for ADV as $w_j > w_e$ and $d_j > d_e$ follow from $e \prec j$ and the definition of the clairvoyant schedule conforming with $O_t$.

Otherwise RG sends $h$, and we claim that (wlog) ADV does the same. Suppose that $j \neq h$, which implies that $w_j < w_h$ and $d_j < d_h$. Then $h \in C_t$, by Fact 2.6. Thus, by Lemma 2.7, $C_t$ remains feasible when $h$ is moved to its very beginning. Hence we assume that ADV transmits $h$ in the current step. No further changes need be made to ADV’s buffer as RG also sends $h$.

Thus in this case the adversary’s expected gain is $w_h$. ■

4. Conclusion and Open Problems

We have shown that, as long as the adversary is oblivious, the ideas of Li et al. [12] can be applied to randomized algorithms, and devised a $\frac{4}{3}$-competitive algorithm this way. However, the gap between the $\frac{5}{4}$ lower bound and our $\frac{4}{3}$ upper bound remains.

Some parts of our analysis hold even in the adaptive adversary model [8]. On the other hand, other parts do not extend to adaptive adversary model, since in general such adversary’s schedule is a random variable depending on the algorithm’s random choices. Therefore it is not possible to assume that this “schedule” is ordered by deadlines, let alone perform reordering like the one in proof of Lemma 2.7.

This makes bridging either the $[\frac{5}{4}, \frac{4}{3}]$ gap in the oblivious adversary model, or the $[\frac{4}{3}, \frac{5}{4}]$ gap in the adaptive adversary model all the more interesting.

Acknowledgements

I would like to thank my brother, Artur Jeź, for numerous comments on the draft of this paper.
