Abstract

Background: Berberine is a plant alkaloid that is widely used as an anti-infective in traditional medicine. *Escherichia coli* exposed to berberine form filaments, suggesting an antibacterial mechanism that involves inhibition of cell division. Berberine is a DNA ligand and may induce filamentation through induction of the SOS response. Also, there is biochemical evidence for berberine inhibition of the cell division protein FtsZ. Here we aimed to assess possible berberine mechanism(s) of action in growing bacteria using genetics tools.

Methodology/Principal Findings: First, we tested whether berberine inhibits bacterial growth through DNA damage and induction of the SOS response. The SOS response induced by berberine was much lower compared to that induced by mitomycin C in an SOS response reporter strain. Also, cell filamentation was observed in an SOS-negative *E. coli* strain. To test whether berberine inhibits FtsZ, we assessed its effects on formation of the cell division Z-rings, and observed a dramatic reduction in Z-rings in the presence of berberine. We next used two different strategies for RNA silencing of ftsZ and both resulted in sensitisation of bacteria to berberine, visible as a drop in the Minimum Inhibitory Concentration (MIC). Furthermore, Fractional Inhibitory Concentration Indices (FICIs) showed a high level of synergy between ftsZ silencing and berberine treatment (FICI values of 0.23 and 0.25 for peptide nucleic acid- and expressed antisense RNA-based silencing of ftsZ, respectively). Finally, over-expression of ftsZ led to a mild rescue effect in berberine-treated cells.

Conclusions: The results argue against DNA binding as the primary mechanism of action of berberine and support the hypothesis that its antibacterial properties are due to inhibition of the cell division protein FtsZ. In addition, the genetic approach used here provides a means to rapidly test the activity of other putative FtsZ inhibitors.

Introduction

Berberine (Figure 1) is an alkaloid produced by several plant species including barberry (*Berberis spp.*) and goldenseal (*Hydrastis spp.*), and is usually found in roots, stems and bark. Berberine has been shown to exhibit antibacterial activity against a variety of bacteria, including many pathogenic species and multidrug-resistant (MDR) strains of *M. tuberculosis* and MRSA. It is also active against some fungi and protozoans. Berberine is used in traditional Chinese, Native American and also in Western medicine, where it is recognised for its antimicrobial properties. In addition, recent studies have revealed tumoricidal and anti-inflammatory activities of the compound [1–9]. Berberine is a relatively weak antimicrobial, especially against Gram-negative bacteria. This is due to it being a substrate for the multi-drug resistance efflux pumps; the presence of MDR pump inhibitors remarkably increases the antibacterial effectiveness of the compound [10]. Despite much data for its antimicrobial activity, the mechanism of action of berberine in bacteria has remained unclear.

A number of studies demonstrate that berberine is a DNA ligand, able to bind both single- and double-stranded DNA in vitro [11–14]. Thus, berberine binding to DNA in bacteria could lead to DNA damage. If so, berberine would induce the bacterial SOS response - a multi-level post-replication DNA repair system. The SOS response involves over 20 genes and is regulated by LexA and RecA. Its purpose is, firstly, to detect DNA damage, activate repair mechanisms like NER (Nucleotide Excision Repair) and, if necessary, to prevent cell division through binding of FtsZ by Sua, resulting in cell elongation. This gives the cell time to repair DNA lesions by inducing a further repair mechanism involving the mutagenic DNA repair polymerase V.

An alternative possible mechanism of action for berberine was reported in a recent study [2] that provides *in vitro* evidence for inhibition of FtsZ, a protein that is key to bacterial cell division. FtsZ assembles into a contractile ring (called the Z-ring) at the midcell site of the future septum [15]. FtsZ is highly conserved among bacteria and is a prokaryotic homologue of eukaryotic tubulin [16,17]. The Z-ring is formed of protofilaments of polymerised FtsZ subunits. FtsZ, like eukaryotic tubulin, is a...
Berberine inhibits FtsZ, we tested the effects of berberine on FtsZ-dependent on a functional SOS response system. To test whether the cell elongation effect of berberine treatment is also an SOS response-negative strain was used to establish was used to report damage caused by berberine in growing cells. DNA binds and damages DNA, an E. coli SOS response reporter strain was used to test whether berberine causes cell elongation, which is an expected effect of cell division inhibition. However, cell elongation can be caused by other factors such as DNA damage and induction of the bacterial SOS response. Therefore, the antibacterial mode of action of berberine requires further elucidation.

Previous studies on the mode of action of berberine were mainly biochemical and included NMR spectroscopy, FtsZ polymerisation and GTPase activity assays, fluorescence and electron microscopy. It was shown that berberine binds to FtsZ with high affinity, inhibits FtsZ assembly and its GTPase activity in vitro. Berberine causes cell elongation, which is an expected effect of cell division inhibition. However, cell elongation can be caused by other factors such as DNA damage and induction of the bacterial SOS response. Therefore, the antibacterial mode of action of berberine requires further elucidation.

There is evidence for both DNA binding and FtsZ inhibition as mechanisms that could explain the antibacterial activities of berberine. Both possibilities are supported by extensive in vitro data, but cellular and genetic evidence is lacking. Here we attempted to test both of these possible mechanisms in live, growing cells through functional assays. To test whether berberine binds and damages DNA, an E. coli SOS response reporter strain was used to report damage caused by berberine in growing cells. Also, an SOS response-negative strain was used to establish whether the cell elongation effect of berberine treatment is dependent on a functional SOS response system. To test whether berberine inhibits FtsZ, we tested the effects of berberine on FtsZ localisation and Z-ring assembly in vivo. Also, we used two types of RNA silencing to reduce ftsZ expression. RNA silencing is a powerful research tool that enables conditional and titratable expression reduction of specific genes and thus aids functional analyses. Here, we applied selective RNA silencers, based both on expressed antisense RNA and peptide nucleic acids (PNA), designed to target ftsZ mRNA [26] and also tested the effects of over-expression of ftsZ on susceptibility to berberine. The findings are consistent with berberine acting as an FtsZ inhibitor.

Materials and Methods

Bacteria, growth conditions and RNA silencing

E. coli wild-type strain K-12 in Mueller Hinton Broth (MHB, Fluka, Germany) was used for PNA (Panagene, Korea) studies. Overnight E. coli cultures were standardised by OD₅₅₀ readings to approximately 10⁸ cfu/ml and then 20 μl was used as inoculum in each well of a 96-well plate (Costar, UK). PNA concentrations (0–2 μM) were optimised for a titration in growth inhibition. Overnight cultures of derivatives of TOP10 E. coli (Invitrogen, UK) carrying plasmids expressing antisense sequences (Table 1) were standardised as above. Antisense expression was induced by IPTG (0, 20, 40 or 70 μM) added to MHB supplemented with chloramphenicol (30 μg/ml). For antisense PNA treatment and IPTG induction, PNA (Table 2) or IPTG in aqueous solution was deposited into wells of a 96-well plate before the addition of 20 μl E. coli in liquid culture to a final volume of 200 μl for a final 10⁶ cfu/ml. Bacterial cultures were grown in a Bio-Tek PowerWave X340I spectrophotometer at 37°C with agitation every 5 min. Growth was monitored by OD₅₅₀ readings every 5 min.

For ftsZ over-expression experiments, E. coli strain DH5α carrying plasmid pBAD-ftsZ (Table 1) was grown as described above with a

series of L-arabinose concentrations. Each condition was performed in triplicate.

Minimum Inhibitory Concentration (MIC) determination

Berberine hemisulphate (Alexis Biochemicals, CA), triclosan (Ciba AG, Switzerland) and mitomycin C (Roche, UK) were added in a series of dilutions to growth medium containing approximately 10^4 cfu/ml of bacteria. MIC was scored as the lowest concentration of an antimicrobial compound at which no growth of the tested *E. coli* strain was observed after 18 hours of incubation in a 96-well plate prepared as described above.

**E. coli** SOS response studies

*E. coli* strain SS996 (Table 3) was grown for 18 hours in a 96-well plate in a Bio-Tek PowerWave X340I spectrophotometer as described above, and levels of GFP fluorescence were measured in a Spectrmax M2 (Molecular Devices, CA) spectrophotometer using 488 nm (excitation) and 520 nm (emission) filters.

Figure 4. Z-ring formation and cell morphology in berberine-treated *E. coli*. Representative cells untreated and treated with 3 mM berberine; FtsZ was tagged with YFP and bacterial DNA was visualised through staining with DAPI. Scale bars are 10 μm.

doi:10.1371/journal.pone.0013745.g004
Fluorescence microscopy

Overnight cultures of E. coli KP7600 (wild-type) and JD26285 (sulA::Tn5 SOS- mutant, see Table 3) were grown in MHB, refreshed 1:50 with fresh MHB medium and then either untreated or treated with different concentrations of berberine hemisulphate (1.5, 2.5 and 3 mM) for 2 hours at 37°C and 200 rpm. The cells were viewed by fluorescence microscopy at 630× total magnification on a DM 4000B fluorescence microscope (Leica, Germany).

For Z-ring formation studies, E. coli strain KG22-pLAU80 (a gift from Professor Kenn Gerdès and Ms Elisa Galli, Newcastle University) containing plasmid pLAU80 (Table 1) carrying a βςζ-yfp fusion was used. An overnight culture was refreshed as above and treated with 3 mM berberine for one hour. 0.2% L-arabinose was added in order to induce production of FtsZ-YFP. After one hour, induction was stopped by addition of 0.2% glucose and the cells were allowed to grow for another 30 minutes. The culture was then harvested by centrifugation; washed three times in an equal volume of 1 × PBS in order to remove the residues of growth medium and berberine, and re-suspended in 1 ml of 1 × PBS. DAPI (Sigma, UK) was added to a final concentration of 1 μM, cells were incubated at room temperature for 10 mins, washed three times with 1 × PBS and viewed under a fluorescent microscope as above. Images were captured and processed using Leica IM 500 and Adobe Photoshop Elements software.

Fractional Inhibitory Concentration Indices (FICIs)
calculations for synergy studies

Fractional Inhibitory Concentrations (FICs) for berberine and the applied gene silencers were calculated as follows:

\[
\text{FIC}_\text{berberine} = \frac{\text{MIC}_\text{berberine} + \text{MIC}_\text{silencer}}{\text{MIC}_\text{berberine}}
\]

\[
\text{FIC}_\text{silencer} = \frac{\text{MIC}_\text{silencer} + \text{MIC}_\text{berberine}}{\text{MIC}_\text{silencer}}
\]

FICIs were determined by adding the FIC values for berberine and each silencer:

\[
\text{FICI} = \text{FIC}_\text{berberine} + \text{FIC}_\text{silencer}
\]

The FICIs represent the level of paired interaction, where ‘synergy’ is defined by values ≤0.5 and ‘no interaction’ by values >0.5–4.0 [27]. The combinations of berberine and silencer were tested in triplicate.

Statistical analysis

Statistical analyses of R² for correlation, mean ± SD calculations and ANOVA were carried out using MS Excel 2007.

Results

Berberine does not induce a significant SOS response in E. coli

Berberine has been reported to be a DNA ligand and some of the effects it has on bacterial cells, particularly cell elongation could be explained by DNA binding/damage and subsequent induction of the bacterial SOS response. Hence, to test the possibility that the mode of action of berberine is a result of its ability to bind DNA, E. coli SS996, an SOS response indicator strain, was used. This strain contains a fusion of the promoter of the SOS response division inhibitor gene sulA with gfp and also an allele of FtsZ that is insensitive to SulA (SulB103) [28]. The strain is negative for SOS-induced cell division inhibition, but the presence of the sulA::gfp fusion allows a measurement of the level of fluorescence, and thereby SOS response induction in the cell caused by a test compound [29]. E. coli SS996 was grown with the addition of different amounts of berberine. For comparison, equal amounts of mitomycin C and triclosan (as a respective percentage of the MIC of each compound which did not cause a significant growth inhibition) were used. Mitomycin C, a potent DNA crosslinker used as an anti-tumour agent, was applied as a positive control. Triclosan, a specific inhibitor of the enoyl-acyl carrier protein reductase (FabI) involved in fatty acid biosynthesis, was used as a negative control. Relative fluorescence of E. coli SS996 treated with the three compounds is presented in Figure 2. Both triclosan and berberine induced virtually no SOS response at doses of up to 4% of their MIC. In contrast, mitomycin C caused a significant level of fluorescence in this dose range, indicating strong induction of the SOS response. The results suggest that berberine induction of the SOS response in bacteria is very low relative to mitomycin C.

Berberine treatment results in cell elongation in an SOS response-negative strain

If berberine causes cell elongation through inhibition of the bacterial division protein FtsZ and not induction of the SOS response, then berberine should also cause elongation in an SOS response-negative strain. To test this possibility, E. coli strain JD26285 (SulA- , SOS-negative) and KP7600 (parent strain, wild-type, Table 3) were cultured either with or without sub-inhibitory concentrations of berberine and examined using fluorescence microscopy. Untreated cells exhibited normal morphology, whereas berberine-treated cells of both strains were significantly elongated (Figure 3). Thus, berberine also causes cell elongation in a strain lacking the SOS response. Together these results argue strongly against the hypothesis that the antimicrobial effect of berberine is due to DNA binding activity.

Berberine inhibits Z-ring formation in vivo

To study the effect of berberine on Z-ring formation, we applied an E. coli strain KG22 carrying pLAU80 (Table 1), which contains an βςζ-yfp fusion. In the absence of berberine, clear Z-rings were visible in many of the observed cells (Figure 4), and some cells exhibited multiple Z-rings and an elongated structure, presumably due to over-abundance or dysfunction of the FtsZ-GFP fusion [30,31]. Most cells displayed one or more Z-rings. Addition of 3 mM berberine heavily perturbed the formation of the Z-rings. The fluorescence was evenly distributed in the cytoplasm of the berberine-treated bacteria, and very few cells displayed the Z-rings. These findings also support the hypothesis that FtsZ inhibition is the main mode of action of berberine in bacteria.

Sensitisation of E. coli to berberine through ftsZ silencing

To examine the mode of action of berberine using gene expression titration experiments, we applied two different, established methods of RNA silencing: expressed antisense RNA and antisense PNA. The specificity of these methods has been examined in several studies and validated silencers have been reported for the E. coli ftsZ gene [26]. E. coli growth was monitored both in the presence and absence of berberine, and with or without ftsZ silencing using PNA and antisense RNA. This strategy was based on the principle that lowering (but not eliminating) the expression of a target gene using antisense technology would cause the bacteria to be more susceptible to an antimicrobial compound targeting the product of that gene. In the case of expressed antisense RNA, E. coli SOS-negative strain JD26285 carrying either plasmid pHNZ (anti-ftsZ), or pHN682 (anti-fabI antisense, control) were grown in the presence of a range of berberine and IPTG (inducer for the antisense RNA expression) concentrations. The growth curves and MICs for different levels of anti-ftsZ RNA expression are presented in Figure 5. Addition of IPTG had a clear inhibitory effect on the growth of cells due to silencing of a growth-essential gene. Silencing of ftsZ prolonged the lag phase and lowered the final OD. Moreover, silencing of ftsZ caused the bacteria to be more sensitive to berberine. Most importantly, upon induction of antisense anti-ftsZ RNA expression, bacterial growth was completely inhibited at a lower concentration of berberine. Silencing of ftsZ expression resulted in a reduction of the MIC of berberine from 4.5 mM without IPTG to 2 mM for 70 μM IPTG, whereas the control strain was not affected by IPTG (MICs were the same within the applied range of IPTG concentrations). In addition, the FIC indices revealed synergy between anti-ftsZ RNA expression and berberine treatment (FICI = 0.23, Fig. 5) and suggest no interaction between berberine addition and silencing of the control gene fabI (FICI = 0.78).

Addition of anti-ftsZ PNA had an effect on bacterial growth that was similar to that observed with expression of anti-ftsZ RNA. In this case wild-type K-12 E. coli strain and PNA targeting ftsZ (Ec326) and fabI (Ec107, control) were utilised. Again, bacteria were sensitised to berberine when the ftsZ gene was silenced by the PNA; the MIC of berberine was reduced from 1.75 mM (no PNA added) to 0.25 mM (2 μM Ec326 added). As a control, silencing of fabI had no effect on cell susceptibility to berberine. Also, FIC indices suggest synergy between silencing of ftsZ and berberine treatment (FICI = 0.25) compared with FICI = 1 for silencing of fabI. Growth curves and linear regression analysis of MIC is shown in Figure 6.

The results from both silencing approaches support the hypothesis that berberine targets the bacterial division protein FtsZ. For comparison, the MICs of berberine for each of the E. coli strains used in this study are presented in Table 3.

Antagonism between ftsZ over-expression and berberine effect on bacterial growth

To establish whether over-expression of ftsZ increases bacterial resistance to berberine, we used E. coli DH5α carrying plasmid pBAD-ftsZ, and DH5α without a plasmid was used to prove a control having basal ftsZ expression. Relative growth rates were calculated as ΔOD/Δt, and cultures were scored after Δt = 10 hours, as further ftsZ over-expression was growth-inhibitory (data not shown). In the case of the strain over-expressing ftsZ without the addition of berberine, an increase in L-arabinose concentration caused a growth rate decrease. This was because ftsZ over-expression is toxic to the cell, presumably due to its crucial and multi-faceted role in cell division [32,26,33,34]. In the presence of arabinose, the addition of berberine increased bacterial growth (Figure 7); the cultures exhibited a moderate increase in the relative growth rate with increasing amounts of L-arabinose. In the case of the control strain, addition of L-arabinose did not rescue bacterial growth from inhibition by berberine. These results indicate that ftsZ over-expression antagonised the toxic effect of berberine, further suggesting that berberine targets FtsZ.

Discussion

The plant-derived isoquinoline alkaloid berberine has a long history of use as an antimicrobial agent. Also, it has been shown to suppress the growth of a variety of tumour cells, and is effective in certain types of diabetes or cardiovascular conditions [6,35–44]. Understanding the mechanism(s) of action of berberine is of significant interest and requires further studies. Berberine is a known DNA and RNA binder [45,11,46,47], and recently it was reported to target the bacterial division protein FtsZ [2]. The evidence supporting these findings was obtained mainly through biochemical and biophysical studies. Here, we aimed to test these two hypotheses for the mode of action of berberine in bacteria using a molecular genetics approach. Firstly, we investigated the possibility that the growth inhibitory properties of berberine are due to its ability to bind to DNA and, therefore, induced bacterial
SOS response. Within the studied range of concentrations, berberine did not cause a significant level of SOS response in the indicator E. coli strain S9996 relative to the positive control. This result is consistent with an earlier study of berberine using the SOS chromotest, which showed that the compound is not a potent genotoxicity or mutagenic agent [16]. Furthermore, berberine caused cell elongation in an SOS-negative strain, as it did in the wild-type strain. Fluorescence microscopy showed berberine to cause disruptions of Z-ring formation in vivo. These findings suggested that FtsZ is the main target for berberine in bacteria. To further test this hypothesis, we studied the relationship between the cellular abundance of the putative target and the effect of berberine on bacterial growth; \( \text{ftsZ} \) expression was titrated using antisense and over-expression tools. Lowering the expression of \( \text{ftsZ} \) resulted in increased susceptibility of the bacteria to berberine and also in a decrease in the MIC. In the control assay, upon silencing of another essential gene, fabI, sensitisation to berberine was not observed. Furthermore, over-expression of \( \text{ftsZ} \), despite high level of toxicity, rescued the growth of berberine-treated cells.

In conclusion, the data argue against DNA binding/damage as the primary mechanism of action of berberine, and argue strongly for inhibition of FtsZ as the primary target for berberine in bacteria.

Acknowledgments

We would like to thank Dr Andrew Hibbert for help with fluorescence microscopy, Ms Liu Yang for technical assistance, and Professor Kenn Gerdes and Ms Elisa Galli for providing plasmid pLAU90.

Author Contributions

Conceived and designed the experiments: JMB, JS LG. Performed the experiments: JMB. Analyzed the data: JMB JS LG. Contributed reagents/materials/analysis tools: JS LG. Wrote the paper: JMB JS LG.
