**ABSTRACT**

Organophosphate hydrolase (OPH), encoded by the organophosphate degradation (*opd*) island, hydrolyses the triester bond found in a variety of organophosphate insecticides and nerve agents. OPH is targeted to the inner membrane of *Brevundimonas diminuta* in a pre-folded conformation by the Twin Arginine Transport (Tat) pathway. The OPH signal peptide contains an invariant cysteine residue at the junction of the signal peptidase cleavage site along with a well conserved lipobox motif. Treatment of cells producing native OPH with the signal peptidase II inhibitor globomycin resulted in accumulation of most of the preOPH in cytoplasm with negligible processed OPH detected in the membrane. Substitution of the conserved lipobox cysteine to serine resulted in release of OPH into the periplasm, confirming that OPH is a lipoprotein. Analysis of purified OPH revealed that it was modified with the fatty acids palmitate and stearate. Membrane-bound OPH was shown to interact with the outer membrane efflux protein TolC and with PstS, the periplasmic component of ABC transporter complex (PstSACB) involved in phosphate transport. Interaction of OPH with PstS appears to facilitate transport of P$_i$ generated from organophosphates due to the combined action of OPH and periplasmically located phosphatases. Consistent with this model, *opd* null mutants of *B. diminuta* failed to grow using the organophosphate insecticide methyl parathion as sole source of phosphate.

Organophosphate Hydrolase (OPH) is a lipoprotein

Membrane-associated organophosphate hydrolase (OPH) hydrolyses the triester bond found in a variety of organophosphate insecticides and nerve agents (1,2). The 39 kDa monomer requires Zn$^{+}$ ions as cofactor (3). OPH is encoded by the opd (organophosphate degrading) gene found on dissimilar plasmids and the opd gene has recently been shown to be a part of an Integrative Mobilizable Element (IME) (4). Due to the mobile nature of the opd island, identical opd genes are found among bacterial strains isolated from different geographical regions (4,5). Though its physiological substrate is unknown, OPH hydrolyzes paraoxon at a rate approaching the diffusion limit ($k_{cat}/K_{M}$ 108 M$^{-1}$ s$^{-1}$) (6). Considering its catalytic efficiency and broad substrate range, it has been assumed that OPH has evolved to degrade organophosphate (OP) insecticides accumulated in agricultural soils (7). Structural analysis shows that OPH contains a TIM barrel fold as seen in most of the members of amidohydrolase superfamily proteins (8).

OPH associates with cell membranes and membrane-associated OPH has been purified from a number of sources (3,9-13). Analysis of the amino acid sequences of OPH proteins indicates that all of them contain a predicted signal peptide harbouring a well-defined twin-arginine (Tat) motif. Twin-arginine signal peptides serve to target proteins to the twin-arginine protein transport (Tat) pathway which translocates folded proteins across the bacterial cytoplasmic membrane (14). ProteinaseK treatment confirmed that OPH is exported to the periplasmic side of inner membrane in B. diminuta and dependence on the Tat pathway was demonstrated since substitution of the invariant arginine residues of the Tat signal peptide affected both processing and localization of OPH (15). However, the mechanism by which OPH is anchored to the inner membrane and the physiological role of OPH are currently unclear. In this report we demonstrate that OPH is a lipoprotein and that it plays an essential role in the acquisition of phosphate from OP insecticides.

EXPERIMENTAL PROCEDURE

**Media, Strains and plasmids**- Strains and plasmids used in the present work are shown in Table 1. Primers used for PCR amplification and site-directed mutagenesis are listed in supplementary Table 1. B. diminuta cultures were grown either in LB medium or in HEPES minimal medium. HEPES minimal medium was prepared by dissolving 0.2 g KCl, 0.2 g MgSO$_4$.7H$_2$O, 40 mg Ca(NO$_3$)$_2$.4H$_2$O, 80 mg (NH$_4$)$_2$HPO$_4$ and 1 mg Fe$_2$SO$_4$ in a litre of 50 mM HEPES, pH 7.4. The medium also contained essential amino acid mixture (0.07 mM), pantothenate (0.5 mg), vitamin B-12 (0.001 mg) and biotin (0.001 mg) along with sodium acetate (2%) as carbon source. The (NH$_4$)$_2$HPO$_4$ was omitted when methyl parathion (0.6 mM) was used as sole phosphate source. When required polymyxin (10 µg/ml), chloromphenicol (30 µg/ml) or tetracycline (20 µg/ml) were supplemented to the growth medium. All chemicals used in this study were procured from Sigma-Aldrich, Bengaluru, unless otherwise specified all restriction and other enzymes used in DNA manipulations were procured from ThermoScientific, USA. Routine DNA manipulations were performed following standard procedures (16).

**Carbonate and urea extraction**- Total membrane preparations were made from B. diminuta by following standard procedures (17). The cytoplasmic membrane was isolated by following the discontinuous sucrose gradient method described elsewhere (18) and equal amounts of membrane was resuspended in buffer containing different concentrations of sodium carbonate, pH 11.5, or urea (2-8 M as indicated). After 1 h incubation at room temperature the samples were centrifuged at 227,226 x g using a TLA 120.2 rotor (Beckman coulter) for 45 min to pellet the washed membranes. Detection of OPH in the wash supernatant and membrane fractions

---
Organophosphate Hydrolase (OPH) is a lipoprotein

was achieved by western blots using anti-OPH antibodies (15). The quantity of OPH in membrane and supernantant fractions were densitometrically determined by comparing with the OPH signal obtained with untreated membrane.

Globomycin treatment- The opd null mutant, B. diminuta DS010 containing the plasmid pSM5 was grown in LB medium to mid log phase (0.6 OD at 600 nm) and 50 µg/ml globomycin (Sigma-Aldrich) was added to the culture medium 1 h before the expression of OPH was induced by addition of 3 mM isopropyl β-D-galactopyranoside (IPTG) (19,20). After 6 h of induction, the culture was harvested, washed in SET buffer (500 mM Sucrose, 5 mM EDTA and 20 mM Tris-HCl, pH 8.0) and used to prepare periplasmic, cytosolic and total membrane fractions as described previously (21,22). OPH specific signals in the subcellular fractions were detected by performing western blot analysis.

Generation of OPHC24S- The invariant cysteine residue in the lipobox motif of the OPH signal peptide was modified to serine by performing quickchange™ site directed mutagenesis (Stratagene). Plasmid pMS5 was used as template and the cysteine to serine codon substitution was confirmed by sequencing. The resulting plasmid coding for OPHC24S was designated pCSOPH. The B. diminuta DS010 (pCSOPH) cultures were grown to mid log phase and the expression of OPHC24S was induced overnight by supplementation with 3 mM IPTG. The cells expressing OPHC24S were subsequently harvested, washed and fractionated into periplasm, cytoplasm and total membrane for the detection of OPH. A similar fractionation procedure was undertaken with B. diminuta DS010 (pSM5) to assess membrane anchorage of OPH in wild type cells.

Solubilization of OPH from the inner membrane- Inner membrane preparations were isolated from a 10 l overnight culture of B. diminuta following procedures described elsewhere (18). The isolated inner membrane was resuspended in minimal amounts of buffer (20 mM Tris-HCl, pH 8.0, 150 mM NaCl, 2% glycerol) and after estimating protein concentration the buffer volume was adjusted to give a final protein concentration of 5 mg/ml. Triton X-100 (2g/g protein), Triton X-114 (2g/g protein), n-Dodecyl β-D-maltoside (DDM) (1g/g protein) and digitonin (8g/g protein) were separately added to aliquots of the membrane suspension and samples were incubated with gentle rotation (10 rpm) for 1 h at 4°C. Subsequently, the samples were subjected to ultracentrifugation (117,000 x g) and the clarified supernatants, containing solubilised protein, were removed into prechilled tubes. The detergent insoluble fraction was resuspended in an equal volume of buffer and the OPH activity was estimated in both detergent soluble and detergent insoluble fractions (3). The percent OPH release from the membrane was calculated by comparing with total OPH activity associated with the untreated membrane. Subsequently, for identification of fatty acids attached to OPH, the protein was solubilized using 1.5% Triton X-100 as it disrupts interactions of OPH with other proteins and facilitates purification of OPH without interacting partners.

Affinity purification of OPH and identification of fatty acids- For purification of OPH-specific antibodies, 10 mg of pure OPH, purified as described elsewhere (23), was coupled to 400 µl of CNBr-activated Sepharose™ 4B (GE healthcare) following the manufacturer’s protocol. Aliquots of OPH antisera (15) were passed through the OPH-coupled Sepharose column at a flow rate of 0.5 ml per minute. The flow-through was collected carefully and reloaded onto the column to ensure complete binding of OPH-specific antibodies to the column. The unbound antibodies and serum proteins were removed by washing the column with three column volumes of wash buffer (20 mM Tris-HCl, pH 7.6). The bound anti-OPH antibodies were eluted (0.1 M glycine-HCl, pH 2.5) as 1 ml fractions into prechilled tubes containing 100 µl of 1 M Tris-HCl,
Organophosphate Hydrolase (OPH) is a lipoprotein pH 9.0 to ensure quick neutralization of the eluate. The antibody fractions were then pooled and dialyzed against coupling buffer (10 mM sodium phosphate, pH 7.2, 150 mM NaCl).

For coupling to proteinA/G beads, Approximately 1 mg of purified anti-OPH antibodies were mixed with 500 µl protein A/G-agarose plus beads (ThermoScientific) equilibrated with coupling buffer and kept for 1 hour at 4°C with gentle shaking. The contents were loaded on to a column and the excess unbound antibodies were removed by washing the column with three column volumes of coupling buffer. The anti-OPH antibodies bound to protein A/G-agarose beads were covalently linked by adding one column void volume of cross-linking buffer (10 mM Sodium phosphate, pH 7.2, 150 mM NaCl, 2.5 mM disuccinimidyl suberate (DSS) to the column. The column was left for one hour at room temperature to complete cross-reaction and the excess DSS were quenched by washing the column with 25 mM Tris-HCl, pH 7.6. The OPH-antibody cross-linked protein-A/G agarose beads were then taken into a clean tube and suspended in 1 ml of prechilled binding buffer (20 mM Tris-HCl, pH 7.6, 150 mM NaCl, 2% glycerol). Immediately, Triton X-100 solubilised membrane proteins of B. diminuta were added to the beads and left overnight at 4°C with head to head rotation. After incubation the contents were loaded onto a column, washed thoroughly with wash buffer and the bound proteins were then eluted with glycine-HCl, pH 2.5 prior to neutralization with 100 mM Tris-HCl, pH 9.0. About 100 µg of immunopurified OPH was esterified using methanolic-HCl (24). The fatty acid methyl esters generated from OPH were then analyzed using Agilent GC/MS equipped with a quadrupole mass selective detector. Control samples were prepared from the periplasmic fraction of B. diminuta DS010 (pCSOPH) and treated identically to identify the fatty acid methyl esters.

Identification of the OPH interactome- To identify interacting proteins, OPH was affinity purified using two different approaches. Before proceeding with the purification of OPH, the cell pellet collected from wild type B. diminuta was resuspended in PBS buffer (1g/10ml) before treatment with 25 mM formaldehyde (25,26). The formaldehyde cross-linked cell pellet was sonicated (10 cycles of 20 sec ON and 40 sec OFF) and the membrane fraction was isolated following established procedures (27). The membrane pellet was extracted three times with 5 ml chloroform:methanol (3:1) and the precipitated proteins were resolubilized in phosphate buffer (0.1 M Phosphate buffer, pH 7.6, 350 mM NaCl, 5% glycerol, 1% DDM and 50 mM Imidazole). The first approach involved immunopurification using anti-OPH antibody cross-linked protein-A agarose beads. The resolubilized cross-linked OPH complex was passed through the column containing the antibody-linked beads at a flow rate of 0.5 ml/minute. The flow through was repeatedly passed through the column until negligible amounts of protein were detected flowthrough sample. After washing the column with three column volumes of wash buffer (20 mM Tris-HCl, pH 7.6, 150 mM NaCl, 2% glycerol, 0.1% DDM), the bound cross-linked OPH complex was eluted as described above, and subsequently analyzed both under native and denaturing conditions. Blue native PAGE (28) and gel filtration (Superose 6, 10/300 GL, GE healthcare) were performed to assess the molecular mass of the OPH complex and Tricine-PAGE (29) was performed to visualise polypeptides coeluting with OPH.

In an alternative approach, a deca-histidine tagged OPH variant (OPH10xHis) was generated. To achieve this, a DNA fragment encoding 10 histidine residues was introduced into the opd gene, between nucleotide positions 420 and 426 that encodes amino acids in a loop region of OPH. First, a BamHI restriction site was introduced into opd by performing quick change mutagenesis between nucleotide positions 420-426 using plasmid pSM5 as template. Next, the synthetic DNA fragment encoding the ten histidine
residues was prepared as a BglII fragment and inserted in-frame into the opd gene at the generated BamHI site. The resultant plasmid was designated pOPH141HIS. Plasmid pOPH141HIS was mobilized into B. diminuta DS010, and B. diminuta DS010 (pOPH141HIS) cells were then induced to express OPH\(^{10xHIs}\) by addition of IPTG at a final concentration of 3 mM. After incubation with IPTG for 5 h the cells were harvested and the cell pellet was resuspended in PBS buffer (1g/10ml) and treated with 25 mM formaldehyde to cross-link OPH. The formaldehyde cross-linked cell pellet was processed as described earlier to obtain total membrane pellet. The pellet was then extracted three times with 5 ml chloroform:methanol (3:1) and the precipitated proteins were resolubilized before loading the soluble proteins onto a Ni-charged immobilised metal affinity column (IMAC). Following washing with phosphate buffer, bound protein was eluted with 500 mM Imidazole in phosphate buffer and analyzed both on blue native and Tricine-PAGE. The affinity purified OPH complexes were subjected to tryptic digestion and mass spectrometry (LTQ-Orbitrap XL ETD mass spectrometer) as described elsewhere (30) to establish the identity of OPH interacting proteins.

**Bacterial two Hybrid system**- Protein-protein interactions were studied by the bacterial two-hybrid system (BACTH, Euromedex) following protocols described elsewhere (31). The T25 and T18 domains were separately fused to the N or C termini of the target proteins (OPH and PstS). The fusions were produced independently by cloning the opd and pstS genes in either pKNT25 or pUT18C. Cells of *Escherichia coli* strain BTH101 (Euromedex) were transformed with different combinations of fusion plasmids i.e. pUT18CPstS-pKNT25OPH and pUT18COPH-pKNT25PstS. The combinations pUT18CPstS-pKNT25 and pUT18COPH-pKNT25 served as controls. β-galactosidase assay was performed as described elsewhere (32).

**Pull-down assay of coexpressed proteins:** Interaction of OPH with phosphate binding protein, PstS and efflux pump component, TolC, was determined by performing coexpression-pull-down assays (33). Initially, an opd gene variant engineered to code for OPH with C-terminal AviTag was generated. Two complementary oligos specifying the AviTag sequence (AviTag-F and AviTag-R; Supplementary Table 1) were annealed, digested with XhoI and HindIII and cloned into similarly-digested plasmid pSM5 to give plasmid pOPHV400 – this procedure results in insertion of the AviTag coding sequence in frame with opd. Next, the opd gene from plasmid pOPHV400 was excised as an EcoRI and HindIII fragment and cloned into one of the multiple cloning sites of pETduet1 vector that had been similarly digested. Subsequently, the birA gene was cloned as an Ndel and XhoI fragment into the second multiple cloning site of this construct. The cloning strategy places birA under the control of T7 promoter, allowing for regulatable expression of biotin ligase, the enzyme required to ligate biotin at the conserved lysine residue of the AviTag. The resulting pETduet1 derivative, designated pAVB400, codes for both OPH\(^{CAviTag}\) and the biotin ligase. The pstS gene was amplified from *B. diminuta* and cloned initially in pET23b as an Ndel-XhoI fragment. The generated recombinant plasmid, pPST300, codes PstS\(^{C6His}\). After confirming expression of PstS\(^{C6His}\), pstS was amplified from pPST300 using primers PstSPMB-F and PstSPMB-R, respectively, and cloned into similarly digested pMMB206 to give plasmid pLPST300, which encodes PstS\(^{C6His}\) controlled by the tac promoter of the vector. *E. coli* ArcticExpress cells harbouring pAVB400 were transformed with pLPST300 and the expression of OPH\(^{CAviTag}\) and PstS\(^{C6His}\) was induced following standard procedures. The total cell lysate was prepared and the clear lysate was used to isolate OPH\(^{CAviTag}\) and any interacting partners using streptavidin magnetic beads (Dynabeads M-280 Streptavidin, Invitrogen) following the
Organophosphate Hydrolase (OPH) is a lipoprotein

manufacturer’s protocols. The proteins bound to magnetic beads were analyzed by 12.5% SDS-PAGE and probed either with anti-OPH or anti-His antibodies to detect OPH\textsuperscript{Cavita}\textsuperscript{g} and Pst\textsuperscript{S6Hs}. Cell lysates prepared either from ArcticExpress (pAVB400) or ArcticExpress (pLPST300) cells treated in similar manner served as controls.

OPH-TolC interactions: The tolC gene was amplified from \textit{B. diminuta} and cloned as a \textit{BglII-EcoRI} fragment into similarly digested pRSETA. As the cloning strategy facilitates in frame fusion of the vector-specified His-tag to tolC, the resulting recombinant plasmid, pTOLC400 codes for Tol\textsuperscript{N6His}. Similarly, the opd gene was amplified from \textit{B. diminuta} as an \textit{EcoRI-HindIII} fragment and cloned into similarly digested pMMB206. The resulting recombinant plasmid, pTLOPH, codes for OPH without any affinity tag, expressed under control of the \textit{tac} promoter. The Tol\textsuperscript{C6His} and OPH were coexpressed by adding 1 mM of IPTG to the mid log phase cultures of ArcticExpress (pTLOPH400 + pTOLC400). Similarly, the expression of Tol\textsuperscript{C6His} and OPH were induced from ArcticExpress (pTLOPH400) and ArcticExpress (pTLOPH400) cells before preparing clear lysate (4 ml) from 50 ml of culture. The lysate was then incubated overnight with 20 µl of MagneHis beads (Promega) at 4$^\circ$C with constant mixing. After incubation, the beads were collected and washed following the manufacturer’s protocol and the presence of Tol\textsuperscript{C6His} and OPH were detected by performing immunoblots probed either with anti-OPH antibodies or anti-His antibodies.

RESULTS

\textit{OPH is tightly bound to the \textit{B. diminuta inner membrane}}- It has previously been demonstrated that OPH is associated with the inner membrane of \textit{B. diminuta} (15). To probe the nature of the interaction of OPH with the membrane, we first determined whether the protein could be released from membrane fractions following washing under alkaline conditions using sodium carbonate (Fig. 1A), or under strong denaturing conditions in the presence of urea (Fig. 1B). At concentrations of sodium carbonate normally used to extract peripheral membrane proteins (0.1-0.5M) (34), very little OPH was released from the membrane, suggesting a relatively tight association with the bilayer. However at higher concentrations of carbonate, significant levels of OPH were released (Fig. 1A). Likewise the protein was also relatively refractory to extraction by urea, with most of the protein remaining associated with the membrane fraction even in the presence of 8 M urea (Fig. 1B). This behaviour is consistent with OPH being an integral protein of the inner membrane rather than associating with the membrane by electrostatic interaction or through binding to other inner membrane proteins.

\textit{OPH is a lipoprotein}- The Tat system is known to assemble some membrane-anchored proteins (20,35,36). In bacteria these usually have either a single transmembrane domain at the C-terminus (35) or an N-terminal non-cleaved twin-arginine signal anchor sequence (37). However, bioinformatic analysis supported by structural studies show that OPH has no C-terminal hydrophobic helical domain (38) and the N-terminal signal peptide of OPH is cleaved off during biosynthesis and therefore cannot serve as a signal anchor (15).

A third class of bacterial membrane proteins that is known to be assembled by the Tat pathway is lipoproteins (20,39,40). \textit{In silico} analysis of the OPH signal peptide, shown in Fig. 2A, predicts the existence of both a SpaseII and multiple SpaseI cleavage sites in pre-OPH, with the SpaseII cleavage site predicted with the highest level of confidence. In addition to the predicted SpaseII cleavage site, a well conserved lipobox containing a cysteine residue was found in the c-region of the signal peptide (Fig. 2A). To determine whether OPH was a substrate of Spase II, we treated cells of \textit{B diminuta} DS010 (pSM5) with globomycin, which inhibits processing of the
Organophosphate Hydrolase (OPH) is a lipoprotein

prolipoprotein by binding irreversibly to the peptidase (20,41). In support of the in silico prediction, in the globomycin-treated cultures most of the OPH accumulated in the cytoplasmic fraction in an unprocessed form (Fig. 2B, lane 1). This is in contrast with the untreated cells where very little precursor was detectable (Fig. 2B, lane 2). Moreover, there was substantially less mature OPH detectable in the membrane fraction following globomycin treatment (Fig 2B, lane 3).

To provide additional evidence that OPH is a lipoprotein, we generated a serine substitution of the essential cysteine in the OPH signal sequence lipobox (OPH<sup>C24S</sup>) and compared the subcellular location of this variant to that of the wild type protein (Fig. 2C,D). Unlike the wild type protein where the mature form is found in membrane fraction (Fig. 2C), most of the processed form of OPH<sup>C24S</sup> was found in periplasm, with very little seen in the membrane (Fig. 2D). Since Spasell acts only on acylated prolipoproteins to generate S-lipidated cysteine at the N-terminus of the mature protein (42), it is assumed that the mature-sized form of OPH<sup>C24S</sup> found in periplasmic fraction results from processing by SpaseI (Fig. 2A), which is predicted bioinformatically to recognise this signal peptide (Fig. 2A). Taken together these results demonstrate that OPH is a membrane-anchored lipoprotein.

**Mature OPH is linked to myristic and oleic fatty acids**- Previous findings have shown that generally diacyl glycerol serves as a lipid anchor for membrane-associated lipoproteins (43). To confirm the nature of the lipid anchor on membrane-bound OPH and to identify the fatty acid modifications, we extracted fatty acids from affinity purified OPH and OPH<sup>C24S</sup> (as a negative control) using methanolic-HCl extraction (24). The fatty acid methyl esters generated due to transesterification were extracted and analyzed using GC-MS. As shown in Fig. 3A and B, two novel peaks were identified arising from the mOPH purified from *B. diminuta* membranes, which were not observed in the control sample derived from OPH<sup>C24S</sup>. These two peaks corresponded to methyl myristate (C14: 0) and methyl oleic acid (C18: 1) with 97% and 99% identities (Fig. 3, C, D, E and F). These results demonstrate that OPH is anchored to the membrane through diacyl-glycerol which is linked with myristic and oleic groups.

**OPH interacts with phosphate ABC transporter**- To gain further clues about the physiological role of OPH, we next sought to identify whether it interacted with other cellular proteins. First we developed a strategy to purify OPH in its native state by dispersing the membrane fraction with the non-ionic detergents Triton X-114, n-Dodecyl β-D-maltoside (DDM) and digitonin. Of the three detergents, DDM facilitated the best release of OPH (liberating approximately 70% of total OPH; data not shown).

Next, we developed a strategy to purify DDM-solubilised OPH. In the crystal structure of OPH the C-terminal region is exposed (38), and we therefore constructed a strain of *B. diminuta* producing OPH with a C-terminal Hexa histidine tag. However the DDM-solubilised OPH<sup>C6His</sup> failed to bind the Ni-NTA column, suggesting that the C-terminus of OPH is not able to interact with the affinity matrix, possibly due to masking of this region by a partner protein subunit. To resolve this problem, we again used the crystal structure of OPH as a reference to introduce an internal decahistidine tag internally into a loop region of OPH. This variant, designated OPH<sup>10xHis</sup>, bound well to the Ni-affinity matrix following solubilisation from the membrane. The affinity-purified OPH<sup>10xHis</sup> sample was further analyzed both by BN-PAGE and gel filtration. These two independent experiments both suggested that OPH<sup>10xHis</sup> was present in a complex of around 294 kDa (Fig. 4A and B). Assuming that the detergent used to solubilise OPH from the membrane may interfere with the determination of an accurate molecular mass for the OPH complex, the isolated membranes from the formaldehyde treated *B. diminuta* DS010 (pOPH141HIS) cells were
Organophosphate Hydrolase (OPH) is a lipoprotein

extracted with methanol:chloroform (3:1) to delipidate the sample and the resulting membrane protein precipitate was resolubilised before proceeding with affinity purification of the cross-linked OPH-complex. BN-PAGE analysis of the OPH-complex isolated in this way coincided with the mass of the OPH complex purified from detergent-solubilized membranes (compare Fig. 4B with Fig. 4C, lane 1).

To validate these findings were employed a second, independent approach to purify untagged OPH. The membranes isolated from the formaldehyde cross-linked *B. diminuta* wild type cells were extracted with methanol:chloroform (3:1) and the resolubilised membrane proteins were passed through a protein-A column that had been crosslinked with OPH-specific antibodies. The size of the OPH complex obtained following this purification process coincided with the BN-PAGE profile of the OPH complex purified following Ni-affinity column (IMAC) (Fig. 4C, lane 3). We therefore conclude that OPH is present in an approximatively 293 kDa complex.

The delipidated OPH complexes purified by immuno-affinity and by IMAC were analysed by Tricine-SDS-PAGE. It can be seen (Fig. 4D) that several protein bands with similar sizes are common between the two samples, although bands with apparent masses of 38 kDa, 35 kDa and 15 kDa are more intense in immuno-purified OPH complex. The 35 kDa protein coincided with the size of OPH and its identity was also established by performing a western immunoblot with anti-OPH antibodies (Fig. 4D).

After establishing that OPH is a multiprotein complex, we performed mass-spectrometry to obtain unique peptide sequences from proteins copurifying with OPH following IMAC. The obtained peptide sequences were identified using either x!tandem or Mascot web servers. Proteins that matched with more than two peptide sequences are listed in Table 2. From the list of proteins, subunits of the F$_{1}$F$_{0}$ATP synthase ($\alpha$, $\beta$, $\gamma$), the phosphate ABC transporter substrate binding protein (PstS) and efflux pump components AcrB and TolC were identified as candidate OPH interacting partners (Table 2). It is interesting to note that the identified peptides matched with proteins involved either in phosphate uptake (44) or in effluxing of xenobiotics (45), as organophosphates are xenobiotics that also contain a potential source of phosphate.

**OPH interacts with phosphate specific transport component PstS**- As PstS is a periplasmic protein that binds specifically to inorganic phosphate, we chose to further probe potential interaction of OPH with PstS. Initially we undertook bacterial two-hybrid analysis to assess OPH-PstS interactions. When PstS was fused to the C-terminus of the adenylate cyclase T18 fragment and OPH to the N-terminus of the T25 fragment, adenylate cyclase activity was reconstituted, and strong $\beta$-galactosidase activity could be measured (Fig. 5A). A similar strong interaction was also seen when OPH was fused to the C-terminus of the adenylate cyclase T18 fragment and PstS to the N-terminus of the T25 fragment. To confirm that OPH and PstS directly interact, we performed coexpression-pulldown assays. To this end we generated compatible plasmids coding for OPH$^{CAviTag}$ (pAVB400) and PstS$^{N6His}$ (pPST300). In addition, plasmid pAVB400 also codes for the biotin ligase, BirA, to facilitate ligation of biotin at the conserved lysine residue of AviTag found at the C-terminus of OPH$^{CAviTag}$. After inducing the production of OPH$^{CAviTag}$, PstS$^{N6His}$ and biotin ligase in the heterologous host *E. coli*, Streptavidin-linked beads were used to isolate biotinylated OPH$^{CAviTag}$. As shown in Fig. 5B, PstS$^{N6His}$ copurified with the biotinylated OPH$^{CAviTag}$ (Fig. 5B, lane 1), but was not purified by the Streptavidin-linked beads in the absence of OPH$^{CAviTag}$ (Fig. 5B, lane 3), providing conclusive proof that OPH and PstS are interaction partners.

**Efflux pump component TolC interacts with OPH**- Analysis of the OPH interactome
Organophosphate Hydrolase (OPH) is a lipoprotein

indicated that efflux pump components AcrA, AcrB and TolC also copurified with OPH isolated from B. diminuta (Table 2). We next sought to assess whether there was a direct interaction between OPH and any of these three proteins by heterologous expression and pairwise copurification studies. Unfortunately, we were unable to express B. diminuta AcrA and AcrB in E. coli. However, TolC with an N-terminal His-Tag was successfully produced in the E. coli ArcticExpress strain. We therefore coexpressed untagged OPH along with TolC^N6His and isolated TolC^N6His from total cell lysates using MagneHis beads. Fig. 5C shows that when TolC^N6His was affinity purified, the mature form of OPH was also copurified (Fig.5C, lane 1). Since OPH produced in the absence of TolC^N6His was unable to interact with the beads (Fig.5C, lane 2), it can be concluded that OPH and TolC can directly interact with each other.

**OPH supports B. diminuta growth with methyl parathion as sole phosphate source:** The enzymatic action of OPH generates alkyl phosphates from a variety of organophosphate insecticides due to its triesterase activity (3). These diesters, like diethyl phosphate, may serve as substrates for periplasmically located phosphatases/diesterases, ultimately generating inorganic phosphate (P_i), raising the possibility that interaction of OPH with PstS facilitates the transport of generated inorganic phosphate into the cell. To examine this further, we investigated the ability of B. diminuta to grow in minimal medium using the OP insecticide methyl parathion as sole source of phosphate. As shown in Fig. 6, B. diminuta DS010 alone was unable to grow using methyl parathion as phosphate source, but when carrying plasmid pSM5, encoding OPH, good growth was seen. These results show that OPH is required to support growth using organophosphates as a source of phosphate.

**DISCUSSION**

In this study we have investigated the interaction of the organophosphate hydrolase, OPH, from B. diminuta, with the cytoplasmic membrane and with other cellular proteins. Our work has clearly shown that OPH is a lipoprotein, and adds to a growing list of Tat-dependent lipoproteins in bacteria and archaea (20,44,47). Interestingly, OPH contains an alanine residue at the +2 position and according to the sorting rules for E. coli lipoproteins (42) should be translocated to the outer membrane by the Lol machinery (the genes for which are found in the genome of B. diminuta). However, a number of exceptions to these sorting ‘rules’ have been seen in other Gram negative bacteria, for example in *Pseudomonas aeruginosa* where lipoproteins having lysine, glycine and glutamine at + 2 position remain attached to the inner membrane (49). It appears for B. diminuta an alanine at +2 position also permits inner membrane retention.

Copurification studies using two independent approaches showed that OPH was present as a large multi-protein complex that includes other inner membrane proteins such as a predicted PhoR-like histidine kinase, periplasmic proteins such as PstS and outer membrane proteins TolC and AcrA. Further support for an OPH complex was provided by demonstrating a direct interaction between OPH and PstS, and between OPH and TolC. Growth studies showed that the indirect liberation of organic phosphates from methyl parathion mediated by OPH can support growth with this compound as sole phosphate source. These findings point to a potential model whereby the triesterase activity of OPH generates phosphodiesters from a variety of OP insecticides which are converted to inorganic phosphates by periplasmically-located phosphatases (Fig. 7). The PstS protein, identified here as an interacting partner of OPH, is a known component of an established phosphotransfer system (44), and it binds to inorganic phosphate, facilitating its transport across the inner membrane. During OPH-mediated hydrolysis of OP insecticides, in
Organophosphate Hydrolase (OPH) is a lipoprotein

addition to alkyl phosphates, aromatic compounds like p-nitrophenol are also generated. Products such as p-nitrophenol are more toxic than the parent compounds and if they are not quickly metabolized they need to be effluxed for the survival of the organism. In this context, OPH interactions with efflux pumps may serve to quickly eliminate toxic degradation products from the intracellular environment.

| pTZ57 R/T | Amp', TA cloning vector                                                  | Fermentas |
| pET23b   | Amp', T7 promoter and a C-terminal 6xHIS-tag                              | Novagen   |
| pETduet1 | Amp', contains two multiple cloning sites downstream of T7 promoter.      | Novagen   |
| pRSETA   | Amp', T7 promoter and a N-terminal 6xHIS-tag                              |           |
| pSM5     | Cm', complete *opd* gene encoding preOPH, cloned in pMMB206 as EcoRI and HindIII fragment | 13        |
| pKNT25   | Plasmid for the expression of C-terminal T25-fusion proteins (Kan')       | 50        |
| pUT18C   | pUT18C Plasmid for the expression of N-terminal T18-fusion proteins (Amp') | 50        |
| pCSOPH   | Cm', derivative of pSM5 encoding OPH<sup>C24S</sup>                      | This work |
| pOPH141HIS | Cm', derivative of pSM5 encoding OPH with 10 histidine residues between 141-142 residues. | This work |
| pUT18COPH | Amp', complete *opd* gene cloned inframe to code for C-terminal T18 fragment. | This work |
| pUT18CPstS | Amp', complete *pstS* gene cloned inframe to code for C-terminal T18 fragment. | This work |
| pKNT25OPH | Km', complete *opd* gene cloned inframe to code for N-terminal T25 fragment. | This work |
| pKNT25PstS | Km', complete *pstS* gene cloned inframe to code for N-terminal T25 fragment. | This work |
| pOPHV400  | Cm', Avi tag coding sequence inserted as XhoI and HindIII fragment in pSM5, codes for OPH<sup>CAviTag</sup> | This work |
Organophosphate Hydrolase (OPH) is a lipoprotein

| Vector | Description | Comment |
|--------|-------------|---------|
| pAVB400 | Amp', *opd* variant coding OPH\textsuperscript{CAviTag} taken as EcoRI and HindIII fragment from pOPHV400 and cloned into one of the two multiple cloning sites of pETduet1. The *birA* gene amplified from *E. coli* as Ndel and XhoI fragment was cloned in the second multiple cloning site. Codes for OPH\textsuperscript{CAviTag}, and BirA ligase. | This work |
| pPST300 | Amp', the *pstS* amplified from *B. diminuta* as Ndel and XhoI fragment was cloned in pET23b. Codes for Pst\textsuperscript{N6His} | This work |
| pLPST300 | Cm', *pstS* amplified from pPST300 as BglII and HindIII fragment cloned in pMMB206 digested with BamHI and HindIII. | This work |
| pTOLC400 | Amp', the *tolC* gene amplified from *B. diminuta* cloned as BglII and EcoRI fragment in pRSETA. Codes for Tol\textsuperscript{C\textsuperscript{N6His}} | This work |
| pTLOPH | Cm', the *opd* gene amplified as EcoRI and HindIII fragment cloned in pMMB206. Codes for untagged OPH under control of the *tac* promoter. | This work |
