The compressive properties of chemical vapor deposited zinc sulfide are studied up to 1050°C for the first time. The specimen with columns parallel to the compression direction fails by shear firstly and then the part below the slip plane is split. The fracture mode changes from intergranular to transgranular as temperature increases. During compression, the load firstly increases rapidly, then decreases gradually, and then drops sharply as displacement increases. The compressive strength decreases as temperature increases. Above 800°C, recrystallization is driven by diffusional processes, which leads to the reduction in compressive strength because of the grown grains and the increase in strain softening as holding time increases. At higher temperatures, diffusional processes are joined by plastic deformation which leads to strain hardening and results in the increase in compressive strength with holding time. This plastic deformation mechanism during recrystallization is observed directly from the load-displacement curve by the high-temperature in-situ compression test for the first time.

Key-words: Zinc sulfide, Chemical vapor deposition, Compressive properties, High temperature, Recrystallization

1. Introduction

Zinc sulfide (ZnS) has a wide bandgap \([E_g = 3.68 \text{ eV at room temperature (RT)}]\)¹ and low-energy fundamental phonon modes.² The former property allows ZnS to transmit visible light and the latter long-wave infrared (IR) wavelengths (8–12 µm). ZnS has thus been the only other material besides diamond that can transmit from visible light to long wave IR wavelengths even to microwave range.³ Besides, cubic ZnS is also optically isotropic.⁴ The unique combination of these properties makes ZnS potential candidate for a range of optical engineering applications, such as, the IR windows, optical thin films, photonic crystals, phosphors, and electro luminescent devices.⁵⁻⁸

Optical grade ZnS is commonly synthesized by chemical vapor deposition (CVD) because of the obvious advantages over other techniques, especially in the ease and accuracy of controlling the stoichiometry and purity of the product.⁵⁻⁸ However, CVD ZnS not only has poor transmission in the visible and 3–5 µm regions, but also has absorption band at 6.5 µm.²,⁵⁻⁸ To improve the transmission properties, post thermal treatments are usually required. How the microstructure of CVD ZnS changes during this process and the resulting improvement in transmission properties have been studied.⁹⁻¹¹ However, the compressive properties at high temperatures in-situ are still not known although it is important for the post thermal treatments.

In addition, the thermal properties of CVD ZnS were reported up to temperatures approach or exceed 1000°C,⁹ but the mechanical properties reported were mainly limited to 600°C.⁹,¹²⁻¹⁰ However, as a potential candidate for the IR side window and radome of high-speed vehicles, CVD ZnS can be subjected to severe aerodynamic heating and services at temperatures >600°C especially in some local regions because of the inhomogeneous temperature distribution in the IR side window and radome.¹¹⁻¹³ As is known, the maximum compressive stress is usually a few times higher than the maximum tensile stress under aerodynamic thermal environments.¹¹⁻¹³ However, it is different from the other bulk ceramics that the compressive strength of ZnS is relatively low.¹⁸⁻²⁰ Thus, the compressive properties become critical in the design and evaluation of ZnS IR side window and radome.

In the present work, the compressive properties of CVD ZnS are studied up to 1050°C for the first time. Recrystallization effects are included. The failure mechanisms being responsible for the mechanical behaviors are analyzed. The results contribute to a broader understand-
ing of the mechanical properties of CVD ZnS at elevated temperatures. At the same time, the study is not only useful for the post thermal treatments of CVD ZnS, but also for the design, application, and evaluation of the CVD ZnS in the IR optical engineering.

2. Experimental procedure

The CVD ZnS specimens used in this study were obtained from Beijing Guojing Infrared Optical Technology, Co., Ltd., Beijing, China, in finished form. The relative density is 99.5%. The detailed preparation processes were published previously. The final specimen dimensions were \(5 \times 5 \times 12.5\) mm (length \(\times\) width \(\times\) height) in accordance with Awaji and Nagano.\(^{25}\) The growth direction is parallel to the height direction. It is worth noting that there is an orientation selection which leads to the (100) crystallographic direction of ZnS perpendicular to the substrate during CVD process. Along this direction, the grains grow more rapidly, leading to the development of columnar structure. For the microstructures of the samples before mechanical tests, see Fu et al.\(^3\)

The compressive properties of CVD ZnS were measured on the ultra-high temperature testing machine developed by the authors.\(^{26}\) The pressure in the high-temperature furnace was vacuumed to <5 Pa, followed by introducing high purity argon (>99.9999%), up to the standard atmospheric pressure. The heating rate is \(\sim 50\) °C min\(^{-1}\). To reach a thermal equilibrium, the specimen was held at each testing temperature for 10 min. Particularly, to study the recrystallization effects, longer holding time (i.e., 30, 60, or 90 min) was used. The temperature fluctuation at each holding temperature was \(<\pm 3\)°C. The beam speed of the test machine was 0.5 mm min\(^{-1}\). In each case, 3–5 specimens were tested based on the dispersion of the results. The microstructures after testing were observed by scanning electron microscopy (SEM; S-4800, Hitachi, Ltd., Tokyo, Japan).

3. Results and discussion

The compressive properties of CVD ZnS from RT to 1050°C were measured. The typical load-displacement curves are shown in Fig. 1. It can be seen that the load firstly increases rapidly, then decreases gradually, and lastly drops sharply as displacement increases. Nonlinear deformation arises before reaching the peak point, followed by strain softening. Both nonlinear deformation behavior and strain-softening phenomenon increase significantly as temperature increases [Fig. 1(a)]. It can be seen that significant strain softening arises above 800°C. CVD ZnS shows a little nonlinearity at 900°C when holding time \(t = 10\) min, but significant nonlinear deformation (i.e., strain hardening) as holding time increases [Fig. 1(b)]. These demonstrate that it is different from the traditional bulk ceramics that linear elastic theory doesn’t apply and nonlinear constitutive relation should be adopted when designing and evaluating the CVD ZnS components in the IR optical engineering, especially at high-temperature conditions.

The compressive strength of CVD ZnS from RT to 1050°C is shown in Fig. 2. One can see that the compressive strength decreases as temperature increases [Fig. 2(a)]. Holding time almost has no effect on the compressive strength below 800°C. Above this temperature, as well known, recrystallization occurs.\(^2\) This leads to the reduction in compressive strength with increasing holding time because of the grown grains [see case of \(T = 800\)°C in Fig. 2(b)]. As temperature increases further, the compressive strength can increase with increasing holding time [see the cases at 900 and 1000°C when holding time changes from 10 to 60 min in Fig. 2(b)]. This should be attributed to the fact that diffusional processes are joined by plastic deformation at higher temperatures, leading to strain hardening, as shown in Fig. 1(b), in which a typical example is the variation of load-displacement curve at 900°C when holding time changes from 10 to 60 min. This recrystallization mechanism was suggested by Karaksina et al.\(^{27,28}\) from the microstructure and porosity changes after post thermal treatments. Here, this plastic deformation mechanism is observed directly from the load-displacement curve by the high-temperature in-situ compression test for the first time.

![Fig. 1. The typical load-displacement curves of CVD ZnS, in (a) \(T = RT–1050\)°C and \(t = 10\) min, and in (b) \(T = 800–1000\)°C and \(t = 10–90\) min.](image-url)
To further analyze the fracture behavior and reveal the failure mechanisms of CVD ZnS at elevated temperatures, the typical samples and SEM photos of the main fragments after testing are shown in Figs. 3 and 4, respectively. During compression, the specimen fails by shear firstly and then the part below the slip plane is split. The specimen is crushed into many small columns between RT and 300°C and is of high-energy fracture [Fig. 3(a)]. However, above 300°C, the column number decreases significantly and a few main parts are resulted [Fig. 3(b)]. From Fig. 4(a), one can see that the fractured surface shows uneven facets evenly in all direction between RT and 300°C. However, above 300°C, grain orientation can be clearly observed on the fractured surface [Fig. 4(b)]. This suggests that CVD ZnS mainly fractures at the interfaces of the columns as temperature increases.

From Figs. 4(a) and 4(c), one can see that the grains grow up at 800°C. At the same time, some voids present. This demonstrates that recrystallization occurs. Similar phenomenon can also be observed at 800°C with $t = 90$ min and 900°C with $t = 10$ min [Figs. 4(d) and 4(e)]. With increased temperature or holding time, the grains further grow up significantly and voids disappear [Figs. 4(f)–4(j)]. It can be seen that grain recombination leads to the formulation of large grain, reduces the grain boundaries thus the resistance for crack propagation, increases the extent of transgranular fracture, and finally results in the strength reduction. Besides, lots of slip evidence can be observed clearly in Figs. 4(f)–4(j). This is consistent with the observed plastic deformation at 900°C with $t = 60$ and 90 min and at 1000°C.
Finally, one can see that apparent geometrical structure change can be observed at 1000°C with \( t = 60 \) and 90 min [Figs. 4(i) and 4(j)] because of significant sublimation. This is why the tests are limited to 1050°C in this work.

4. Conclusions

The compressive properties of CVD ZnS with columns parallel to the compression direction were investigated from RT to 1050°C for the first time. The load firstly increases rapidly, then decreases gradually, and lastly drops sharply as displacement increases. Nonlinear deformation occurs before reaching the peak point. After that strain softening arises. Both nonlinear deformation behavior and strain-softening phenomenon increase significantly as temperature or holding time increases because of recrystallization. The compressive strength decreases as temperature increases. Above 800°C, the compressive strength decreases as holding time increases because that grains grow up during recrystallization. As temperature increases further, the compressive strength can increase with holding time as diffusional processes are joined by plastic deformation which leads to strain hardening. This plastic deformation mechanism during recrystallization is observed directly from the load-displacement curve by the high-temperature in-situ compression test for the first time.
