INTRODUCTION

Autophagy, a catabolic cellular process, contributes to recycling and clearance of macromolecules and organelles via the lysosomal degradation system (Boya et al., 2013). Damaged organelles or macromolecules are engulfed by autophagosomes that are enveloped by two layers of membranes, and these structures later fuse with lysosomes to form autolysosomes (Klionsky et al., 2012). Their contents are then degraded by various lysosomal enzymes, and the macromolecular building blocks and metabolites are recycled (Singh and Cuervo, 2011). Autophagy is ongoing at basal levels within cells, but is induced under unfavorable circumstances (Mizushima et al., 2008; Singh and Cuervo, 2011; Klionsky et al., 2012; Boya et al., 2013; Lim and Song, 2014). In mammalian reproduction and development, autophagy is implicated in the maintenance of primordial follicles, blastocyst cavitation, and fetal survival at birth (Lim and Song, 2014). Moreover, cold stress during vitrification and maternal diabetes induce autophagy in mammalian oocytes (Adastra et al., 2011; Bang et al., 2014; Tsukamoto et al., 2014). The activation of autophagy is important for turning over maternal proteins to newly synthesized embryonic ones during preimplantation embryonic development (Tsukamoto et al., 2008). Further, dormant blastocysts activate autophagy for their prolonged survival during delayed implantation (Lee et al., 2011a).

Cryopreservation of oocytes is a crucial tool for the preservation of fertility. Based on the conditions of freezing, there are two major methods for oocyte cryopreservation: slow freezing and vitrification (Saragusty and Arav, 2011). For vitrification, membrane-permeable cryoprotectants (CPAs) such as dimethyl sulfoxide (DMSO), ethylene glycol (EG), and propanediol (PROH) are combined with non-permeable agents such as sucrose and trehalose (Jo et al., 2011). Ultrastructures, nuclear changes, and spindle structures are common parameters used to assess the quality of cryopreserved oocytes (Gualtieri et al., 2011; Martinez-Burgos et al., 2011). We recently showed that autophagy is
induced in vitrified oocytes during warming, and that this induction is not associated with the presence of CPAs or sugars in the reagents used (Bang et al., 2014). This result showed, for the first time, that cold stress during freezing is a potent inducer of autophagy. However, it remained to be determined whether modulation of autophagy affects the subsequent fertilization and development favorably or adversely.

The mammalian target of rapamycin (mTOR) is a crucial regulator of cell growth and metabolism. mTOR is connected with diverse signaling pathways governing cell survival, growth, metabolism, transcription, translation, and autophagy. Therefore, mTOR is considered central to cellular signaling networks (Kapahi et al., 2010). Activated mTOR is phosphorylated, targeting downstream factors such as p70 S6 kinase (S6K) and eukaryotic initiation factor eIF4E-binding protein 1 for their subsequent phosphorylation and activation (Yu et al., 2010). mTOR is also a well-known negative regulator of autophagy. In fact, its inhibition with rapamycin, an immunosuppressive natural product, induces autophagy in various cell systems (Castedo et al., 2002; Yang and Klionsky, 2010). Phosphorylation of mTOR is mediated by S6K, and rapamycin suppresses mTOR-mediated translation by inhibiting the S6K activity (Chiang and Abraham, 2005). In metaphase II (MII) oocytes and preimplantation mouse embryos, autophagy and mTOR activation are inversely correlated, i.e., mTOR activity is high in MII oocytes and suppressed after fertilization, while autophagy displays the opposite trend (Tsukamoto et al., 2008; Yamamoto et al., 2014).

We previously showed that vitrified mouse oocytes show heightened autophagy during warming, and suggested that it is a natural adaptive response to cold stress (Bang et al., 2014). The use of 3-methyladenine, a widely used inhibitor of autophagy, during warming did not have a significant effect on the survival, fertilization, and development of vitrified-warmed oocytes (Bang et al., 2014). However, it remained to be identified whether enhanced or defective autophagy in MII oocytes affects the rates of in vitro fertilization (IVF) and development of vitrified oocytes. In this follow-up work, we investigate how the modulation of autophagy with rapamycin during vitrification affects the rates of vitrification-warming and IVF and development.

MATERIALS AND METHODS

Mice

All mice were maintained in strict accordance with the policies of the Konkuk University Institutional Animal Care and Use Committee (IACUC). This study was approved by the Konkuk University IACUC (approval number KU14099). Mice were sacrificed under avertin to minimize suffering. Four-week-old virgin imprinting control region (ICR) female mice and ten-week-old ICR male mice were purchased from Orient-Bio (Seongnam, Korea).

Collection of matured oocytes

Four-to-five-week-old virgin ICR female mice were intraperitoneally injected with 7.5 IU of pregnant mare’s serum gonadotropin (Sigma-Aldrich, St. Louis, MO, USA) to induce folliculogenensis, followed by injection with 7.5 IU of human chorionic gonadotropin 48 h later to induce superovulation. Next, cumulus-oocyte complexes were collected from the oviducts 13 to 14 h post injection. The MII phase oocytes were retrieved in Quinn’s Advantage Medium with HEPES (Sage, In Vitro Fertilization, Trumbull, CT, USA) containing 20% fetal bovine serum (FBS; Gibco, Grand Island, NY, USA) at 37°C. The cumulus cells were then removed by using 300 μg/mL hyaluronidase (Sigma-Aldrich, USA).

Vitrification and warming procedure

The vitrification and warming procedure was essentially followed as described previously (Bang et al., 2014). The vitrification solution contains a mixture of EG (Sigma-Aldrich, USA) and DMSO ( Sigma-Aldrich, USA). First, the oocytes were pre-equilibrated with a solution of 7.5% EG, 7.5% DMSO, and 20% FBS for 2.5 min; and then equilibrated with 15% EG, 15% DMSO, 20% FBS, and 0.5 M sucrose (Fisher Scientific; Fair Lawn, NJ, USA) for 20 s. Equilibrated oocytes were loaded onto cryotop (Kitazato Corporation, Shizuoka, Japan) and immersed in liquid nitrogen (LN2). The vitrified oocytes were stored in LN2 for 2 weeks. After 2 weeks, they were warmed serially with sucrose solutions of decreasing concentrations (0.5, 0.25, 0.125, and 0 M) and 20% FBS for 2.5 min each. The vitrified-warmed oocytes were then cultured for 1 to 2 h in medium with HEPES containing 20% FBS for recovery.

Western blot analysis

For each group, 100 MII oocytes were directly collected in 35 μL 2×sodium dodecyl sulfate (SDS) sampling buffer (100 mM Tris-Cl [pH 6.8], 4% SDS, 20% glycerol, 2% β-mercaptoethanol, and 0.2% bromophenol blue). The samples were boiled and centrifuged briefly, and then loaded onto 8% SDS-polyacrylamide gels. After electrophoresis, gels were blotted onto nitrocellulose membranes (Millipore, Billerica, MA, USA). These membranes were then blocked with 5% skimmed milk in Tris-base saline for 1 h at room temperature and incubated with primary antibodies at 4°C overnight. They were then incubated with peroxidase-conjugated secondary antibodies (GenDEPOT, Barker, TX, USA) diluted to 1:10,000 for 1 h. Chemiluminescence signals were detected using the
LAS3000 system (Fujifilm, Tokyo, Japan) and quantified by Multi Gauge software (Fuji Film, Japan). The primary antibodies used were: rabbit polyclonal anti-total-mTOR (1:1,000, Cell Signaling Technology, Danvers, MA, USA), rabbit polyclonal anti-p-mTOR (Ser 2448) (1:1,000, Cell Signaling Technology, USA), and mouse monoclonal anti-α-tubulin (1:1,000, Sigma-Aldrich, USA).

**Immunofluorescence staining and confocal microscopy**

Cultured oocytes were fixed and permeabilized with 4% paraformaldehyde with 0.1% Triton X-100 in phosphate-buffered saline (PBS) for 20 min, and washed twice with 0.1% Triton X-100 in PBS for 5 min each. The oocytes were then blocked in 2% bovine serum albumin (BSA)/PBS drop for 1 h. Next, they were incubated with the primary antibody drop containing either anti-p-mTOR (rabbit polyclonal, 1:200; Cell Signaling Technology, USA), anti-Light chain 3 beta (LC3b) (rabbit polyclonal, 1:400; Cell signaling Technology, USA) or anti-Beclin1 (rabbit polyclonal, 1:200; Novus Biologicals, Littleton, CO, USA) in 2% BSA/PBS overnight at 4°C. The oocytes were washed thrice in 2% BSA/PBS for 5 min each, and incubated with Alexa Fluor 488 chicken anti-rabbit secondary antibody (1:250; Molecular Probes, Trumbull, CT, USA) in 2% BSA/PBS for 40 min. After three washes, the oocytes were counterstained with TO-PRO-3-iodide (1:250; Life Technologies, Invitrogen, Carlsbad, CA, USA). They were then washed in 2% BSA/PBS, directly placed on a glass slide, and covered with a glass coverslip that was sealed with transparent nail polish. Rabbit IgG was used as mock control. Immunofluorescence images were obtained using LSM710 confocal microscope (Carl Zeiss, Oberkochen, Germany), and analyzed using Zen 2009 Light Edition, a platform associated with the confocal microscope. For quantification of p-mTOR puncta, each oocyte was imaged at four planes (3 μm intervals) using LSM710 confocal microscope (Carl Zeiss, Germany).

**Rapamycin treatment of oocytes and experimental groups**

Rapamycin (Millipore) was dissolved in DMSO (Sigma-Aldrich, USA). We set up two experimental schemes as shown in Figure 1. Experiment 1: rapamycin-pretreated oocytes were vitrified and warmed, and recovered by culturing for 1 to 2 h at 37°C in 5% CO2. They were then fertilized in human tubal fluid (HTF) containing 10% substitute protein serum (SPS) for 6 h in vitro, washed, and cultured in KSOM-AA (Millipore, Danvers, MA, USA) at 37°C in 5% CO2. Experiment 2: the vitrified oocytes were warmed in warming solutions containing 100 nM rapamycin, and recovered by culturing in medium with HEPES containing 20% FBS and 100 nM rapamycin for 1 to 2 h at 37°C in 5% CO2. Control oocytes underwent the same procedure with solutions containing the same volume of DMSO. Vitrified-warmed oocytes were fertilized in vitro, washed, and cultured in KSOM-AA at 37°C in 5% CO2.

**In vitro fertilization and embryo culture**

IVF was performed according to the procedure described by Cha et al. (2011). Epididymal sperms were obtained from 10 to 11 week-old male ICR mice. For capacitation, a drop of sperm suspension was added in Quinn’s Advantage Fertilization Medium (HTF, Sage, Trumbull, CT, USA) containing 10% SPS (Sage) for 90 min at 37°C in 5% CO2. For IVF, the capacitated sperm suspension was added to oocytes in HTF containing 10% SPS. After 6 h, the oocytes were washed four times with HTF containing 10% SPS and finally, with KSOM-AA medium. They were then cultured in KSOM-AA drops overnight. Fertilization was confirmed 24 h later by observing two-cell embryos. They were cultured for 5 days to assess embryonic development.

**Statistical analyses**

All data were graphed using GraphPad Prism (version 5). The statistical analyses were performed using Student’s t-test (one-tailed). The criteria for statistical significance
RESULTS

Timing of rapamycin treatment: experimental groups

Rapamycin indirectly induces autophagy by inhibiting mTOR, a major suppressor of autophagy (Neufeld, 2010). To identify whether induction of autophagy by rapamycin treatment has a positive or negative effect on the survival, fertilization, and development of vitrified-warmed mouse oocytes, rapamycin was added at two different points as follows: Experiment 1, prior to vitrification; and Experiment 2, during warming (Figure 1). The effects of rapamycin on mTOR phosphorylation and autophagic induction were confirmed by western blotting and immunofluorescence staining (see sections below).

Rapamycin treatment reduces phosphorylation of mTOR in fresh and vitrified-warmed metaphase II oocytes

Prior to assessing the effect of rapamycin on IVF and development of vitrified oocytes, we first examined whether our treatment regimen was effective enough to suppress mTOR phosphorylation in MII oocytes. To address this, we performed immunofluorescence staining and western blotting of total and phospho(p)-mTOR in MII oocytes treated with 100 nM rapamycin. As shown in Figure 2, p-mTOR signals are observed as puncta in the ooplasm (Sancak et al., 2008). The overall expression of p-mTOR in rapamycin-treated oocytes were lower than that in control (fresh and DMSO-treated). Figure 2B illustrates western blotting of p-mTOR; p-mTOR levels decreased in both MII oocytes treated with 100 nM rapamycin for 2 h (Experiment 1), and vitrified-warmed ones treated with the same during warming (Experiment 2). As shown, rapamycin significantly reduced the number of p-mTOR puncta.

Figure 2. Rapamycin treatment suppresses phosphorylation of mammalian target of rapamycin (mTOR) in metaphase II (MII) oocytes. (A) Immunofluorescence staining of p-mTOR in oocytes. Rapamycin was used at 100 nM. Control oocytes were treated with the same amount of vehicle (dimethyl sulfoxide). Oocytes were stained with rabbit polyclonal anti-p-mTOR antibodies (1:200). Alexa Flour 488 chicken anti-rabbit IgG was used as the secondary antibody. DNA was stained with TO-PRO-3-iodide (1:250). Green, p-mTOR; red, DNA. Scale bar, 20 μm. The experiment was repeated 6 times using at least 20 oocytes in each group. Two representative images from each group are shown. Rabbit IgG was used as mock control and did not produce any signal (data not shown).While arrows indicate some examples of p-mTOR puncta. (B) Western blotting of mTOR in oocytes. MII oocytes (100 per group) in Experiments 1 and 2 were collected in SDS sampling buffer. Total lysates were loaded onto 8% polyacrylamide gels and subjected to western blotting with anti-mTOR, anti-phospho (p)-mTOR, and anti-α-tubulin antibodies. This experiment was repeated thrice with similar results.
formed in both groups compared with that in the control groups. Collectively, these results confirm that the treatment condition adopted effectively reduces phosphorylation of mTOR in fresh and vitrified-warmed oocytes.

**Rapamycin treatment in metaphase II oocytes prior to vitrification reduces fertilization rate**

We then confirmed if rapamycin treatment induces autophagic activation in the MII oocytes. In Experiment 1, MII oocytes were incubated with 100 or 250 nM rapamycin in DMSO for 2 h prior to vitrification. The oocytes were then subjected to immunofluorescence staining with anti-LC3 antibody. LC3 is a marker for autophagic activation and generally exhibits puncta formation in the cytoplasm (Mizushima et al., 2004). As shown in Figure 3A, treatment with rapamycin increased the LC3 immunofluorescence at both 100 and 250 nM concentrations, the difference being more evident in case of the former. The oocytes with or without rapamycin treatment were then subjected to vitrification (2 weeks), warming, and IVF. While the survival rates of vitrified-warmed oocytes were similar among the groups (Figure 3B), fertilization rates were markedly reduced (Figure 4). Developmental rate to the blastocyst stage was also reduced in the 250 nM rapamycin-treated group. Thus, exposure to rapamycin prior to vitrification at MII increases autophagy, and negatively affects fertilization and developmental rates *in vitro*.

**Rapamycin treatment in vitrified metaphase II oocytes during warming mildly affects fertilization and developmental rates**

MII oocytes in Experiment 2 received rapamycin treatment (100 nM) during warming and a recovery time of 80 to 90 min after vitrification (Figure 1). To confirm enhanced autophagic response in the rapamycin-treated oocytes, immunofluorescence staining of LC3 and Beclin1 was performed (Figures 5A and B). As shown, expressions of both the markers increased in presence of rapamycin. These oocytes were then subjected to IVF and development. As Figure 6 illustrates, fertilization and developmental rates significantly decreased in the rapamycin-treated group. Thus, rapamycin-caused enhanced autophagy beyond

physiological levels during warming after vitrification exerts a negative effect on fertilization and development.

**DISCUSSION**

In this work, we report that rapamycin treatment causes enhancement of autophagy beyond the physiological level in MII oocytes and that this in turn negatively influences both fertilization and developmental rates of vitrified-warmed mouse oocytes. Rapamycin is a natural product of the bacterium Streptomyces hygroscopicus with immunosuppressive effects (Heitman et al., 1991). As a suppressor of mTOR complex 1 (mTORC1), rapamycin is widely used to induce autophagy (Choi et al., 2014) in oocytes and embryos (Lee et al., 2011b; Song et al., 2014). Meanwhile, mTOR also has several indicated roles in oocyte biology (Lee et al., 2012; Kogasaka et al., 2013; Mayer et al., 2014). A recent work showed that inhibition of mTOR activity during meiotic progression of immature oocytes causes spindle anomaly and chromosome misalignment (Susor et al., 2015). Rapamycin, used at 100 nM for 12 h, showed an inhibitory effect on the translation of specific transcripts associated with meiotic progression, but did not interfere with the overall protein synthesis (Susor et al., 2015). In our study, we used rapamycin in mature MII oocytes for 1 to 2 h before and after vitrification, and observed that fertilization and developmental rates are affected by this brief exposure (Figures 4 and 6). Such short exposure was sufficient to reduce mTOR phosphorylation and increase autophagic activation, and did not cause distinct morphological or cellular abnormalities (Figures 2 to 5) as in immature mouse oocytes (Susor et al., 2015). Our observations, however, do not preclude the possibility that observed effects of rapamycin may have caused undetected side effects.

MII oocytes have been shown to maintain low levels of autophagy until fertilization (Tsukamoto et al., 2008). Within 4 h of fertilization, autophagy is activated to produce new maternal proteins needed for embryonic development. Therefore, defective autophagy in oocytes lacking Atg5 gene negatively affects preimplantation embryonic development by impeding protein turnover during oocyte-to-embryo transition (Tsukamoto et al., 2008). A recent work by Yamamoto et al. (2014) has shown that the mTOR complex1 (mTORC1) activity is relatively high in MII oocytes and decreases rapidly after fertilization, exhibiting an inverse correlation with autophagy (Yamamoto et al., 2014). The authors used alternative inhibitors of mTOR such as Torin1 and PP242 to increase autophagy in MII oocytes and embryos, but were unsuccessful. Thus, they suggested that fertilization-induced autophagy is independent of mTORC1 activity.

![Figure 4. Effect of rapamycin pretreatment on fertilization and development of vitrified-warmed oocytes. Graphs show the percentage of 2-cell embryos and blastocysts after in vitro fertilization. The table shows the total number and percentage of oocytes that were used in the barograms. Data represent the mean of six independent experiments (n = 6), while error bars represent the mean±standard deviation (SD). Statistical significance was analyzed by Student’s t test (one-tailed). * p<0.05, ** p<0.01.](image-url)
In our experiment, rapamycin treatment increased autophagy in MII oocytes, but this induction is not essentially associated with fertilization. Thus, the distinctive results are most likely caused by differences in timing of treatment regimen as well as the type and dose of inhibitors used. Rapamycin was also used in a study on porcine oocytes, which induced slight increases in LC3-II expression. This treatment was shown to improve cytoplasmic and nuclear maturation in porcine oocytes by increasing autophagic activation (Song et al., 2014). Thus, mTOR is associated with regulation of autophagy in mammalian oocytes.

In conclusion, our data suggest that heightened autophagy beyond a physiological response during warming...
after vitrification has a negative effect on fertilization and development. We propose that the extent of autophagic activation in MII oocytes could further be developed as a marker to predict developmental competence after cryopreservation. Cryopreserved MII oocytes with little or no autophagic activation may thus predict better embryo quality.

CONFLICT OF INTEREST

We certify that there is no conflict of interest with any financial organization regarding the material discussed in the manuscript.
