Abstract

The ability to flexibly navigate an environment relies on a hippocampal-dependent internal cognitive map. Explored space can be internally mapped at different spatial resolutions. However, whether hippocampal spatial coding resolution can be dynamically controlled within and between environments is unknown. In this work we recorded the firing of hippocampal principal cells in mice navigating virtual reality environments, which differed by the presence of local visual cues (virtual 3D objects). Objects improved spatial coding resolution globally with a higher proportion of place cells, smaller place fields, increased spatial selectivity and stability. Spatial coding resolution was notably enhanced locally near objects and could be rapidly tuned by their manipulations. In the presence of objects, place cells also displayed improved theta phase precession and theta timescale spike coordination. These results suggest that local visual cues can rapidly tune the resolution of the hippocampal mapping system within and between environments.
Introduction

Animals can flexibly navigate their environment. In mammals such as rodents and humans, this ability is thought to rely on an internal cognitive map (Tolman, 1948; O’Keefe and Nadel, 1978; Epstein et al., 2017). When animals move in their environment, hippocampal place cells fire in specific locations (their place fields) and this spatial tuning is believed to provide a neuronal substrate to the cognitive map. To be useful for navigation, such internal representation should be properly oriented and positioned in reference to the external world. Distal visual cues or intramaze objects located at the border of an environment play a predominant role in map orientation while environmental boundaries are important for map anchoring (O’Keefe and Burgess, 1996; Knierim and Rao, 2003; Knierim and Hamilton, 2011). A dynamic control of hippocampal spatial coding resolution between environments or different regions of the same environment could be important for spatial navigation (Geva-Sagiv et al., 2015). Spatial coding resolution can be improved by increasing the proportion of spatially selective cells (place cells) coding for these locations (e.g. overrepresentation), by reducing place field size but also by enhancing their spatial selectivity, stability and spatial information content. Wild animals, including rodents, often travel kilometers away from their home through empty space to specific food locations (Taylor, 1978). Mapping all traveled space at similar spatial resolution would require a huge neuronal and computational investment. Alternatively, mapping different parts of an environment at different spatial resolutions could be advantageous. Previous studies have reported increased place field density near rewarded locations (O’Keefe and Conway, 1978; Hollup et al., 2001; Dupret et al., 2010; Danielson et al., 2016; Sato et al., 2018), salient sensory cues (Wiener et al., 1989; Hetherington and Shapiro, 1997; Sato et al., 2018) or connecting parts in multi-compartment environments (Spiers et al., 2015). Whether these overrepresentations correspond to position coding at higher spatial resolution (i.e. the resolution of the “where” information) or the coding of nonspatial information associated with these particular locations (also referred to as “what” information) is difficult to disentangle. If they would represent increased spatial resolution, then place fields should not only be more numerous but they should also more accurately code for space in terms of spatial selectivity, spatial information content and stability. Furthermore, in the context of navigation, spatial coding resolution should be rapidly adjustable within and between
environments. Finally, improved spatial coding resolution should extend to the temporal
coding domain.

The factors controlling spatial coding resolution are poorly understood. Local sensory
cues, with a higher sensory resolution compared to distal cues, could be instrumental in this
process according to sensory-based models of place cell activation (O’Keefe and Burgess,
1996; Hartley et al., 2000; Barry et al., 2006; Geva-Sagiv et al., 2015; Strösslin et al., 2005;
Sheynikhovich et al., 2009). Here we took advantage of virtual reality (Holscher, 2005;
Youngstrom and Strowbridge, 2012; Chen et al., 2013; Ravassard et al., 2013; Aronov and
Tank, 2014; Cohen et al., 2017) to specifically control and manipulate local sensory cues and
test their impact on hippocampal spatial coding resolution. We recorded a large number of
hippocampal cells in area CA1 to be able to use decoding strategies to decipher the
functional impact of the changes observed. Our results show that local visual cues (virtual 3D
objects) increased spatial coding resolution globally with a higher proportion of place cells,
improved spatial selectivity, information content and stability. Spatial coding resolution was
notably enhanced near objects with a higher local density of place fields but also decreased
place field size and stability. Spatial resolution could be instantaneously tuned upon removal
or addition of local cues. Importantly, increased spatial coding resolution extended to the
temporal coding domain. Altogether our results suggest that the hippocampal system can
rapidly and dynamically adjust its spatial coding resolution within and between
environments.
Results

Effects of local visual cues on spatial coding resolution

Head-fixed mice were trained to run on a wheel and to shuttle back and forth on a 2 m-long virtual linear track to collect liquid rewards at its extremities (Fig. 1A). The lateral walls of the virtual track displayed distinct visual patterns to provide directional information. However, these patterns did not provide any information relative to the position of the animal on track. To investigate the contribution of local cues to hippocampal spatial representation, mice were trained either in the presence or absence of 3D visual cues (hereafter called virtual objects; Object Track, OT: n = 2 mice; No Object Track, ØT: n = 3 mice), which were virtually positioned on the floor of the track between the animal trajectory and the walls (Fig. 1B). The running wheel forced the animals to run in a unidirectional manner so that they repetitively ran along the virtual objects without the possibility to orient toward them or explore them with any sensory modality but vision. Animals received a reward (sucrose in water 5%) each time they reached one of the extremities of the linear track. After licking, the mice were “teleported” in the same position but facing the opposite direction of the track (Fig. 1C), allowing them to run back and forth in the same environment. Once animals reached a stable and proficient behavior (at least 1 reward/minute during a 60 min-long session), we recorded spiking activity in the pyramidal cell layer of the CA1 hippocampal region using either 4-shanks or 8-shanks silicon probes (Fig. 1A, Figure 1-figure supplement 1) in the right and/or left hemispheres over the course of 2-3 days. A total of 1124 neurons were recorded in the CA1 pyramidal cell layer. Mice trained in ØT (n = 9 recording sessions) performed the task with similar proficiency than mice trained in OT (n = 5 recording sessions), as shown by similar rate of reward collections (ØT: 1.70 ± 0.29 rewards/minute, n = 9 recording sessions in 3 mice; OT: 1.15 ± 0.09 rewards/minute, n = 5 recording sessions in 2 mice; t_{12} = 1.40, P = 0.19, two-tailed unpaired t-test; all values expressed as mean ± SEM) and average running speed (ØT: 14.1 ± 2.12 cm/s, n = 9 recording sessions in 3 mice; OT: 16.8 ± 1.58 cm/s, n = 5 recording sessions in 2 mice; Z = -1.27, P = 0.24, two-tailed Wilcoxon rank sum (WRS) test; Fig. 1C).

To examine how local visual cues impacted spatial representation of the linear track we first compared the number of track-active putative pyramidal cells to assess for overall excitability and the proportion of place cells among them to assess for spatial resolution. The
percentage of track active cells was comparable in between the track without and with virtual objects (ØT: 66.4 ± 5.8%, n = 7 sessions in 3 mice; OT: 52.8 ± 7.8%, n = 5 sessions in 2 mice; \( t_{10} = 1.43, P = 0.18 \), two-tailed unpaired \( t \)-test; Fig. 1D). However, while only 19% of track active cells had at least one place field (place cells) in the empty track (n = 48 place cells), 73% of track active cells were place cells when virtual objects were present (n = 103 place cells; \( t_{10} = -7.2, P < 10^{-4} \), two-tailed unpaired \( t \)-test; Fig. 1E). In ØT, place fields were relatively sparse in the middle of the track with a large proportion of them aligned either to the beginning or to the end of the track (End-Track fields: 49.3 ± 8.99%, n = 7 sessions in 3 mice; Fig. 2A). In the maze with objects, however, the majority of fields was located in the central part of the track (On-Track fields: 84.3 ± 1.50%; n = 5 sessions in 2 mice; \( Z = 2.03, P = 0.048 \), two-tailed WRS test; Fig. 2A). These results indicate that local visual cues can strongly increase the proportion of place cells among active cells notably to code the central part of the maze.

Another factor influencing spatial resolution is place field size. There was a tendency for place field width (calculated on complete fields) to be lower in the track with objects (ØT: 51.5 ± 3.33 cm, n = 15 place fields; OT: 44.6 ± 1.60 cm, n = 95 place fields; \( Z = 1.92, P = 0.055 \), two-tailed WRS test; Fig. 1G), in agreement with a higher spatial coding resolution. Decreased place field width could be due to spatial shrinking of place fields detected on a trial-by-trial basis, could result from decreased inter-trial variability in their position, or both. To decipher among these possibilities, we detected place fields on single trials then calculated their size and averaged them to get a single value for each place field(Cabral et al., 2014). The size of place fields based on single trial detection was not significantly different between the two conditions (ØT: 34.4 ± 1.2 cm, n = 15 place fields; OT: 33.5 ± 0.6 cm, n = 94 place fields; \( Z = 1.1, P = 0.28 \), two-tailed WRS test). On the other hand, the spatial dispersion of single-trial detected place fields was significantly reduced in the presence of 3D objects (ØT: 11.9 ± 0.90 cm, n = 48 place cells; OT: 7.58 ± 0.55 cm, n = 103 place cells; \( Z = 4.25, P < 10^{-4} \), two-tailed WRS test; Fig. 1H). These results suggest that the decreased place field size resulted from decreased inter-trial spatial dispersion. To further assess inter-trial place field stability, independently from place field detection, we calculated a stability index (based on spatial correlations between all pairs of firing rate vectors, see Materials and methods section). This stability index was significantly lower in the track without objects (ØT: 0.12 ± 0.01, n = 48 place cells; OT: 0.34 ± 0.02, n = 103 place cells; \( Z = -7.26, P < 10^{-12} \),
Figure 1: Effects of virtual 3D objects on spatial coding resolution

A. Schema of the virtual reality set up. The mouse is head-fixed and located on a wheel surrounded by LCD screens where a virtual environment is displayed. B. Top and first person views of virtual linear tracks used. Left: track without objects (OT) and right: track with virtual 3D objects (OT). C. Top: Animal’s position in the virtual track as a function of time. Green lines indicate times when animal was in a reward zone location. These locations were not considered for further analysis. Solid and dotted black lines indicate back and forth trials respectively. Top view of animal in the maze is depicted on the right. Arrows indicate teleportation in the same position but facing opposite direction after reward consumption. Bottom: Animal’s speed as a function of time. D, E. Box plots of the percentage of active cells (D; P = 0.18, two-tailed unpaired t-test) and place cells (E; P < 10^-4, two-tailed unpaired t-test) in the maze without (blue) and with (orange) objects (same color code throughout the figures). F. Spike raster plots (top) and color-coded firing rate map (middle) for successive trials in one direction (arrow) as a function of the position in the maze. Bottom: corresponding mean firing rate by positions. Dots indicate positions of the detected place field (see Material and Methods). G-K. Box plots of the place field width (G; P = 0.055, two-tailed Wilcoxon rank sum (WRS) test), the place field dispersion (H; P < 10^-4, two-tailed WRS test), the stability index (I; P < 10^-12, two-tailed WRS test), the out/in field firing rate (J; P < 10^-4, two-tailed WRS test) and the spatial information (K; P < 10^-9, two-tailed WRS test). For box plots in this and subsequent figures, box extends from the first (Q1) to the third quartile (Q3) with the band inside showing the median and the extremities of the whiskers include values greater than Q1-1.5*(Q3-Q1) and smaller than Q3 + 1.5*(Q3-Q1).
two-tailed WRS test; Fig. 1I). Altogether, these results demonstrate that local visual cues can improve inter-trial spatial stability.

An increase in spatial coding resolution would also be associated with higher spatial selectivity and information content. Spatial selectivity was assessed by comparing the in-field versus out-of-field firing rates (i.e., signal to noise ratio) for place fields recorded in OT and ØT. In the track without objects, place cells increased their firing rate inside the place field (7.44 ± 0.75 Hz, n = 48 place cells) but also discharged at high rate outside the field (5.23 ± 0.62 Hz; Fig. 1F and J; ratio: 0.65 ± 0.02). In comparison, place cells recorded in the track with objects had comparable firing rates inside the place field (6.73 ± 0.61 Hz, n = 103 place cells; Z = 1.67, P = 0.1, two-tailed WRS test) but fired significantly less outside the field (3.53 ± 0.49 Hz; ratio: 0.42 ± 0.02; Fig. 1F and J; Z = 3.99, P < 10^{-4}, two-tailed WRS test).

Accordingly, spatial information (in bit/spike), a measure independent of place fields’ detection (William E. Skaggs and Bruce L. McNaughton and Katalin M. Gothard and Etan J. Markus, 1993) was very low in the track without object (0.06 ± 0.01 bit/spike, n = 48 place cells) and significantly higher in the presence of objects (0.32 ± 0.03 bit/spike, n = 103 place cells; Z = -6.29, P < 10^{-9}, two-tailed WRS test; Fig. 1K). Similar results were obtained with a different method to estimate spatial information content based on the original mutual information metric with a normalization to correct possible bias due to differences in basal firing rates between conditions (Souza et al., 2018) (ØT: 1.66, n = 48 place cells; OT: 6.62, n = 103 place cells; Z = -7.36, P < 10^{-12}, two-tailed WRS test).

Altogether these results indicate that local visual cues can strongly enhance the proportion of place cells among active cells but also place cell’s coding accuracy in agreement with an improved spatial coding resolution.

**Virtual 3D objects improve spatial resolution locally**

We then wondered whether 3D objects could enhance spatial resolution locally within the same environment. To address this question, we focused our analysis on On-Track fields recorded in the OT. We first noticed that the distribution of these fields was non-uniform on the track (P = 0.001, test of non-uniformity). To quantify more precisely this effect, we divided the linear track in Objects Zones (OZ) and No Objects Zones (ØZ), depending if a given track zone contained an object or not, respectively (Fig. 2A, right). The density of place fields was significantly higher in OZ (OZ: 8.80 ± 1.09% /10 cm, n = 12 spatial bins of 10 cm, 6
Figure 2: Virtual 3D objects improve spatial resolution locally

A. Color-coded mean firing rate maps of all place fields recorded in the maze without objects (left) or with objects (right). The color codes for the intensity of the bin’s mean firing rate normalized on the maximal mean firing rate (peak rate) in the recording session. The place cells are ordered according to the position of their peak rate in the track (reward zones excluded). Bottom: The tracks were divided into Objects Zones (OZ, in red on the x-axis) around the objects and No Object Zones (ØZ, in grey on the x-axis) deprived of objects. Red dotted lines depict the boundaries of the OZ in the track with objects. B. Percentage of On-Track place fields at each spatial bin (10 cm) in the maze with (orange line) and without objects (blue line). C. Mean local stability index (solid lines) ± SEM (shaded bands) for place cells with On-Track fields at each spatial bin in the track with (orange) or without (blue) objects. D-F. Box plots depicting the mean percentage of place fields per spatial bin (D; $P < 10^{-4}$, two-tailed unpaired t-test), the place field width (E; $P = 0.00016$, two-tailed WRS test) and the local stability index (F; $P < 10^{-5}$, two-tailed WRS test) in OZ and ØZ in the maze with objects.
in each direction; $\bar{\sigma}_Z$: 3.17 ± 0.70% /10 cm, n = 20 spatial bins of 10 cm, 10 in each direction;

$t_{30} = -4.54$, $P < 10^{-4}$, two-tailed unpaired $t$-test; Fig. 2B and D). Furthermore, in the maze with

objects, place fields were significantly smaller in $\bar{\sigma}$ (38.4 ± 1.46 cm, n = 50 fields) compared to $\bar{\sigma}_Z$ (51.6 ± 2.62 cm, n = 45 fields; $Z = 3.71$, $P = 0.00016$, two-tailed WRS test; Fig. 2E).

Accordingly, place field dispersion was also significantly reduced in $\bar{\sigma}$ (7.15 ± 0.59 cm, n = 87 fields) compared to $\bar{\sigma}_Z$ (10.0 ± 0.99 cm, n = 49 fields; $Z = 2.53$, $P = 0.011$, two-tailed WRS test). A local stability index (see Materials and methods section) was significantly increased in $\bar{\sigma}$ (0.56 ± 0.02, n = 60 bins of 2 cm, 30 in each direction) compared to $\bar{\sigma}_Z$ (0.44 ± 0.01, n = 100 bins of 2 cm, 50 in each direction; $Z = -4.68$, $P < 10^{-5}$, two-tailed WRS test; Fig. 2C and F).

Finally we found no significant difference in the out-of-field versus in-field firing ratio between fields located in $\bar{\sigma}$ or $\bar{\sigma}_Z$ ($\bar{\sigma}$: 0.45 ± 0.03, n = 87 fields; $\bar{\sigma}_Z$: 0.41 ± 0.03, n = 49 fields; $Z = -0.62$, $P = 0.54$, two-tailed WRS test) nor changes in spatial information ($\bar{\sigma}$: 0.36 ± 0.04 bit/spike, n = 87 fields; $\bar{\sigma}_Z$: 0.28 ± 0.04 bit/spike, n = 49 fields; $Z = -0.68$, $P = 0.50$, two-tailed WRS test). These results indicate that 3D objects can locally improve spatial coding resolution through a local increase in place field number, a local reduction in place field size and an higher local stability while their effect on spatial information content is more global.

We next wondered whether similar local effects on spatial coding resolution could be observed in the $\bar{\sigma}_T$. In this track place fields were also non-uniformly distributed ($P = 0$; test of non-uniformity) with a higher density of fields at the ends of the track (i.e. End-Track fields; Fig. 2A). However, we found no significant difference between End-Track and On-Track fields in terms of out-of-field versus in-field firing ratio (End-Track: 0.65 ± 0.02, n = 31 fields; On-Track: 0.63 ± 0.03, n = 32 fields; $Z = -0.04$, $P = 0.97$, two-tailed WRS test) and stability (End-Track: 0.17 ± 0.01, n = 31 fields; On-Track: 0.15 ± 0.02, n = 32 fields; $t_{51} = 0.77$, $P = 0.45$, two-tailed unpaired $t$-test). Spatial information was low for both types of fields but paradoxically lower for End-Track fields (End-Track: 0.04 ± 0.01 bit/spike, n = 31 fields; On-Track: 0.09 ± 0.02 bit/spike, n = 32 fields; $Z = -2.54$, $P = 0.01$, two-tailed WRS test). We conclude that overrepresentation of the ends of the $\bar{\sigma}_T$ is not associated with increased spatial coding accuracy and is unlikely to represent increased spatial coding resolution at these locations.

Local visual cues improve hippocampal population coding accuracy
Figure 3: Virtual 3D objects improve hippocampal population coding accuracy

A. Left: Color-coded distribution of the animal position's probability in the virtual track (the reward zones are excluded) computed using a Bayesian decoder (see Material and Methods) at each time window (500 ms) illustrated during 4 trials in the maze without (top) and with (bottom) objects. Spike trains of active cells were used to compute the animal position's probability. For visualization purpose, position probability is normalized by its maximum at each time bin. The real position is indicated with a solid grey line. Right: Confusion matrix between the real (x-axis) and the decoded position (y-axis) for all recording sessions performed on the track without objects (top) or with objects (bottom).

B. Box plots depicting the Bayesian decoding error (BD error) in the maze with and without objects. The BD error was significantly higher in the maze deprived of objects ($P < 10^{-23}$, two-tailed WRS test).

C. Box plots depicting the Bayesian decoding accuracy (BD accuracy) in the maze with and without objects. The BD accuracy was significantly higher in the maze with objects ($P < 10^{-41}$, two-tailed WRS test).

D. Mean BD accuracy (solid lines) ± SEM (shaded bands) as a function of a subset of active cells in the maze with and without objects. The BD accuracy was significantly higher in the maze with objects ($P < 10^{-41}$, two-tailed WRS test).

E. Mean BD accuracy (solid lines) ± SEM (shaded bands) at each position in the maze with and without objects. The track was divided in two zones: Objects Zone (OZ, in red on the x axis) around the objects and No Object Zone (ØZ, in grey on the x axis) deprived of objects. Note that the decoding accuracy was specifically improved in OZ in comparison to ØZ in the maze with objects ($P < 10^{-6}$, two-tailed WRS test).
The results so far suggest that objects can increase the resolution of hippocampal spatial representation. To verify this, we next performed position-decoding analysis (Brown et al., 1998; Zhang et al., 1998) (Fig. 3A). We used the spike trains from all pyramidal cells recorded (i.e., both the spatially modulated and nonspatially modulated cells) and compared decoded positions with actual positions of the animal in the virtual linear tracks. Overall, the effect of objects on hippocampal spatial coding was obvious because the decoding error across trials was nearly two-fold larger in the track without objects compared to the track with objects (ØT: 46.3 ± 0.05 cm, n = 180 trials; OT: 27.6 ± 0.12 cm, n = 129 trials; Z = 10.1, P < 10^{-23}, two-tailed WRS test; Fig. 3A and B). Accordingly, the decoding accuracy (van der Meer et al., 2010) was three fold lower in the empty track compared to the track with objects (ØT: 0.017 ± 2.8 X 10^{-5}, n = 180 trials; OT: 0.053 ± 2.06 x 10^{-4}, n = 129 trials; chance level 0.01; Z = -13.7, P < 10^{-41}, two-tailed WRS test; Fig. 3A and C). In both cases, downsampling was performed to equalize the number of cells used for decoding between the two conditions (20 active cells). These effects were independent of the decoding method used because similar results were observed using a Firing Rate Vector (FRV) method (Wilson and McNaughton, 1993; Middleton and McHugh, 2016). Correlation values were lower in the empty track (ØT: 0.63 ± 0.008, n = 180 trials; OT: 0.74 ± 0.01, n = 129 trials; Z = -8.62, P < 10^{-17}, two-tailed WRS test) and decoding errors were higher (ØT: 48.4 ± 0.67 cm, n = 180 trials; OT: 33.0 ± 1.81 cm, n = 129 trials; Z = 7.32, P < 10^{-12}, two-tailed WRS test). Because Bayesian decoding was performed using a drop cell approach we could measure decoding accuracy for different sample sizes of active cells (van der Meer et al., 2010) (Fig. 3D). Decoding accuracy was positively correlated with sample size in the track with objects but not in the track without objects (Fig. 3D). Importantly, in the track without objects, the decoding accuracy never reached values observed for the track with objects, even when using a larger set of cells (up to 45). To see if objects could locally increase spatial decoding accuracy we compared decoding accuracy between OZ and ØZ. While decoding accuracy was uniformly low in the track without objects (OZ: 0.019 ± 0.0014, n = 30 spatial bins of 2 cm; ØZ: 0.016 ± 9.25 x 10^{-4}, n = 50 spatial bins of 2 cm; Z = 1.42, P = 0.16, two-tailed WRS test; Fig. 3E), it was increased in every part of the track with objects but significantly more in OZ compared to ØZ (OZ: 0.063 ± 0.003, n = 30 spatial bins of 2 cm; ØZ: 0.043 ± 0.002, n = 50 spatial bins of 2 cm; Z = 4.99, P < 10^{-6}, two-tailed WRS test; Fig. 3E). We concluded that local visual cues can globally and locally improve spatial coding accuracy at the population level.
Figure 4: Effects of online object manipulation

A. Mosaic plots representing the cells classified as place cells (darker orange and blue) or non-coding cells (i.e. silent or active non-coding, lighter orange and blue) in the familiar and the new mazes. B-G. Box plots comparing familiar (empty box) and new mazes (filled box) conditions. Two pairs of box plots are illustrated; Left: comparison between the familiar maze without objects (blue, OT_{fam}) and the new maze with objects (orange, OT_{new}). Right: comparison between the familiar maze with objects (orange, OT_{fam}) and the new maze without objects (blue, OT_{new}). A gradient color arrow shows the way of the transition. Plots show the percentage of active cells (B; OT_{fam} vs OT_{new}: P = 0.66; OT_{fam} vs OT_{new}: P = 0.14, two-tailed paired t-test), the percentage of place cells (C; P < 10^{-5} and P = 0.04, respectively, two-tailed paired t-test), the Out/In field firing rate (D; P = 0.06 and P = 0.047, respectively, two-tailed WRS test), the spatial information (SI; E; P = 0.0014 and P = 0.015, respectively, two-tailed WRS test), the place field dispersion (F; P < 0.0004 and P = 0.0008, respectively, two-tailed WRS test) and the stability index (G; P < 10^{-5} and P = 0.0002, respectively, two-tailed WRS test). H. Color-coded mean firing rate maps of place fields recorded in the familiar and new mazes. The color codes for the intensity of the firing rate normalized by the peak rate. The place fields are ordered according to the position of their peak rate in each track (the reward zones are excluded). The tracks were divided into Objects Zones (OZ, in red on the x-axis) around the objects and No Object Zones (ØZ, in grey on the x-axis) deprived of objects. Red dotted lines depict the boundaries of the OZ in the track with objects. I. Mean local stability index (solid orange or blue lines) ± SEM (blue or orange shaded areas) at each spatial bin in the familiar and new mazes (top: from OT_{fam} to OT_{new}; bottom: from OT_{fam} to OT_{new}). J. Map similarity (see Material and Methods) for 10 trials before and 10 trials after the experimental manipulation (indicated by 0) for OT_{fam} to OT_{new} (top) and for OT_{fam} to OT_{new} condition (bottom).
Effects of online virtual objects manipulation

Place cells usually appear instantaneously upon exploration of a new environment in area CA1 (Wilson and McNaughton, 1993). To see if similar dynamics could be observed for the effects of virtual objects on spatial resolution we manipulated objects online while recording the same ensemble of cells in area CA1. For mice trained in an empty track, we instantaneously added the three objects (which were thus new to the mice) after 20 back and forth trials. Conversely, for mice trained in the track with objects we instantaneously removed the three objects. Objects manipulation had no effect on the proportion of active cells (Fig. 4B) but a strong impact on the proportion of place cells (Fig. 4A and C). For mice trained in an empty track, adding objects instantaneously increased the proportion of place cells (from 21.6 ± 5.3% to 75.0 ± 4.1%; n = 5 sessions in 3 mice; t₄ = -35.8, P < 10⁻⁵, two-tailed paired t-test; Fig. 4A and C). Thus, a large proportion of cells initially silent or active but nonspatially modulated in the familiar empty track became spatially modulated (40.3%).

Most of these cells had on-track fields (81.3%; Fig. 4H). A majority of cells initially spatially modulated remained place cells (75.7%) while the others became nonspatially modulated or silent. Adding objects also increased place cells’ spatial information (Z = -3.20, P = 0.0014, two-tailed WRS test; Fig. 4E) and stability (Z = -4.68, P < 10⁻⁵, two-tailed WRS test; Fig. 4G).

Local stability was significantly higher in OZ when objects were added (OZ: 0.56 ± 0.02, n = 60 bins of 2 cm, 30 in each direction; ØZ: 0.25 ± 0.02, n = 100 bins of 2 cm, 50 in each direction; Z = -8.56, P < 10⁻¹⁶, two-tailed WRS test; Fig. 4I) but not before (t₁₅₈ = 0.15, P = 0.88, two-tailed unpaired t-test). Place fields’ out/in field firing ratio and dispersion were instantaneously decreased (Z = 1.86, P = 0.06 and Z = 3.55, P = 0.0004, respectively, two-tailed WRS test; Fig. 4D and F). On the other hand, removing objects decreased the proportion of place cells (from 73.1 ± 6.62% to 39.4 ± 16.4%, n = 5 sessions in 2 mice; t₄ = 2.94, P = 0.04, two-tailed paired t-test; Fig. 4A and C). The spatial information and stability were decreased by this manipulation (Z = 2.44, P = 0.015 and Z = 3.72, P = 0.0002, respectively, two-tailed WRS test; Fig. 4E and G) while place field out/in field firing ratio and dispersion were increased (Z = -1.99, P = 0.047 and Z = -3.31, P = 0.0008, respectively, two-tailed WRS test; Fig. 4D and F). However, even after object removal, local stability was still significantly higher in OZ (OZ: 0.34 ± 0.02, n = 60 bins of 2 cm, 30 in each direction; ØZ: 0.24 ± 0.02, n = 100 bins of 2 cm, 50 in each direction; t₁₅₈ = -3.7, P = 0.0003, two-tailed unpaired
Figure 5: Effects of virtual 3D objects in a visually enriched environment

A. Schema (top) and picture (bottom) representing the original maze with objects (left) and a visually enriched maze with objects (right). B. Color-coded mean firing rate maps for all place fields recorded in the original maze with objects (orange, left) and on the visually rich maze with objects (yellow, right). The color codes for the intensity of the firing rate normalized by the peak rate. The place fields are ordered according to the position of their peak rate in each track (the reward zones are excluded). The tracks were divided into Objects Zones (OZ, in red on the x-axis) around the objects and No Object Zones (ØZ, in grey on the x-axis) deprived of objects. Red dotted lines depicts the boundaries of the OZ. C-H. Box plots representing in the original (orange) and visually rich (yellow) maze with objects the percentage of active cells (C; \( P = 1 \), two-tailed WRS test), the percentage of place cells (D; \( P = 0.20 \), two-tailed unpaired t-test), the out/in field rate (E; \( P = 0.57 \), two-tailed WRS test), the spatial information (SI; F; \( P = 0.67 \), two-tailed WRS test), the place field dispersion (G; \( P = 0.06 \), two-tailed WRS test) and the stability index (H; \( P = 0.95 \), two-tailed WRS test). I. Mean local stability index (solid orange or yellow lines) ± SEM (orange or yellow shaded bands) at each position’s bin in the original (orange) and visually rich (yellow) mazes. J. Mean BD accuracy (solid lines) ± SEM (shaded bands) at each spatial bin in the original maze with objects (orange) or in the visually rich maze with objects (yellow).
t-test; Fig. 4I). We conclude that the effects of local visual cues on place cells’ coding observed between familiar tracks can be reproduced with instantaneous objects manipulation.

We next investigated the dynamic of these changes by correlating the firing rate maps of each back and forth trial with the corresponding average firing rate map in the condition with objects (the most stable condition) for 10 trials before (t-1 to t-10) and 10 trials after (t+1 to t+10) the manipulation (Fig. 4J). When objects were added in the empty track, map similarity was significantly higher for the second trial in the new condition (t-1 vs t+1, n = 598 pyramidal cells; Z = 3.49, P = 0.09; t+1 vs t+2, n = 614 pyramidal cells; Z = 3.71, P = 0.04; Kruskall-Wallis one-way test with post-hoc Bonferroni test) and then stayed higher from this second trial on (t+2 vs t+3, n = 608 pyramidal cells; P = 1, Kruskall-Wallis one-way test with post-hoc Bonferroni test). Conversely, when objects were removed from the familiar track with objects, map similarity dropped already for the first trial in the new condition (t-1 vs t+1, n = 380 pyramidal cells; P < 10⁻⁸, Kruskall-Wallis one-way test with post-hoc Bonferroni test) and stayed lower from this first trial on (t+1 vs t+2, n = 380 pyramidal cells; P = 1, Kruskall-Wallis one-way test with post-hoc Bonferroni test). Thus, the hippocampus can rapidly adapt its spatial coding resolution to local visual cues available in the environment.

**Low proportion of landmark vector cells in OT**

Newly activated place cells could correspond to landmark vector (LV) cells, which have been recorded in the hippocampus of freely moving rats (Deshmukh and Knierim, 2013) and head-fixed mice running on a treadmill (Geiller et al., 2017). These cells tend to discharge systematically near objects present in the environment or landmarks on the treadmill. To test this hypothesis, we specifically looked for LV cells in our recordings. On individual unidirectional trials the presence of LV cells firing near a specific object would be difficult to disentangle from the firing of a place cell which happen to have a place field near that object by chance. Because LV cells tend to systematically discharge near objects, these cells should discharge near the same object (s) in both back and forth trials. We thus used back and forth trials to address this point. We defined object zones for each individual object (IOZ, which were enlarged on the side from which animals were approaching the object to take into account the anticipatory nature of some LV cells (Geiller et al., 2017). Place cells were

Top: Distribution of the maximum cross-correlations used to quantify the frequency shift for all the cells. E. Examples of cross-correlograms computed for two pairs of place cells with overlapping place fields at the behavioral (top) or theta time scale (bottom, see Methods) in order to quantify Cross-Correlogram (CCG) and theta Offsets respectively in no object (blue; left) or object (orange; right) conditions. F. Relationship between ‘CCG’ and ‘theta’ offsets in the cross-correlograms of all the spikes in overlapping place fields of neuron pairs recorded in no object (top; blue; $R = 0.18$, $P = 0.377$, Pearson correlation) and object condition (bottom; orange; $R = 0.44$, $P < 0.001$, Pearson correlation).
classified as LV cells if they were bidirectional (firing in back and forth trials) and had one or more place field(s) in an IOZ corresponding to the same object for back and forth trials. In the track without objects no LV cells were detected. In the track with objects, LV represented only 6.79% of all place cells. This corresponds to the proportion of LV cells recorded in area CA1 in the presence of real objects (Deshmukh and Knierim, 2013). Thus, the vast majority of newly activated place cells in the presence of objects does not behave like LV cells.

**Effects of virtual objects in a visually enriched environment**

We next wondered whether the hippocampal mapping resolution was maximal in the presence of objects or whether it could be further increased by visually enriching the environment. We thus analyzed hippocampal place cells’ coding in another environment containing the original 3D objects but enriched in visual cues such as different wall patterns in different positions along the track and high 3D columns outside the track (EOT, n = 3 mice; Fig. 5A). The percentage of active cells was not increased by visually enriching the environment (OT, n = 5 sessions in 2 mice; EOT, n = 5 sessions in 3 mice; Z = -0.1, P = 1, two-tailed WRS test; Fig. 5C) nor was the percentage of place cells (OT, n = 5 sessions in 2 mice; EOT, n = 5 sessions in 3 mice; t = -1.38, P = 0.20, two-tailed unpaired t-test; Fig. 5B-D).

However, place fields were uniformly distributed along the track in the visually rich environment (n = 16 spatial bins of 10 cm; P = 0.23, test for non-uniformity), thus not clustered around objects as in the visually poor environment (Fig. 5B). This suggests that local visual cues are important to set place fields’ position (Renaudineau et al., 2007). However, all other attributes of place fields were not significantly different between the two environments (OT, n = 103 place cells; EOT, n = 132 place cells; out/in field firing ratio: Z = 0.57, P = 0.57; Spatial info: Z = 0.42, P = 0.67; Dispersion: Z = -1.88, P = 0.06; Stability: Z = -0.06, P = 0.95; two-tailed WRS test for all; Fig. 5E-H). When looking at local stability of firing rates, we still observed a significant effect of objects in the visually enriched environment in OZ versus ØZ (OZ, n = 60 spatial bins of 2 cm; ØZ: n = 100 spatial bins of 2 cm; Z = -2.46, P = 0.014, two-tailed WRS test; Fig. 5I). Interestingly, positions near objects were also decoded with a better accuracy using a Bayesian decoder than positions further away in the visually enriched environment (OZ: 0.08 ± 0.007, n = 30 spatial bins of 2 cm; ØZ: 0.059 ± 0.002, n = 50 spatial bins of 2 cm; Z = 3.08, P = 0.002, two-tailed WRS test; Fig. 5J). Altogether these
results suggest that in the presence of local visual cues, hippocampal spatial coding is not further improved by visually enriching the environment. However, place fields locations are influenced by additional visual cues along the track. Interestingly, despite a homogeneous distribution of place field locations, 3D objects could still locally influence hippocampal population decoding accuracy.

**Hippocampal phase precession is strongly reduced in the absence of virtual 3D objects**

The results so far suggest that local 3D objects can increase spatial coding resolution when considering the spatial firing rate code. Place cells however do not only increase their firing rate inside the place field but also tend to fire at progressively earlier phases of the theta oscillation as an animal moves through the place field (O’Keefe and Recce, 1993). This phenomenon, called theta phase precession, is thought to further increase spatial coding resolution because different locations within the place field that are difficult to distinguish based on firing rate alone can be accurately separated when phase is taken into account. In the temporal domain, increased spatial resolution would thus correspond to increased slope of the phase versus position relationship for identical field sizes.

We first looked for differences in the theta oscillation recorded in the Local Field Potential (LFP) between the two conditions. The mean frequency of the field theta oscillation was not significantly different when mice were running in the track with or without objects (ØT: 6.79 ± 0.12 Hz, n = 9 sessions in 3 mice; OT: 6.77 ± 0.10 Hz, n = 5 sessions in 2 mice; Z = 1.14, P = 0.30, two-tailed WRS test) but was lower than that reported for mice navigating in real linear tracks (Middleton and McHugh, 2016). The power of theta oscillation (theta index see Materials and methods section) was also not significantly different (ØT: 3.31 ± 0.23, n = 9 sessions in 3 mice; OT: 3.55 ± 0.22, n = 5 sessions in 2 mice; t_{12} = -0.69, P = 0.50, two-tailed unpaired t-test). Theta frequency was not modulated by running speed of the animal in ØT (r = 0.02 ± 0.02, n = 9 sessions in 3 mice; Figure 6- figure supplement 1A, C) as previously observed in virtual linear tracks when only distal cues are present (Ravassard et al., 2013). Theta frequency-speed modulation was however significant in OT (r = 0.14 ± 0.03, n = 5 sessions in 2 mice; t_{12} = -2.99, P = 0.01, two-tailed unpaired t-test; Figure 6- figure supplement 1A, C). In contrast, theta amplitude was similarly
modulated by running speed in both conditions (ØT: \( r = 0.06 \pm 0.03, n = 9 \) sessions in 3 mice; OT: \( r = 0.1 \pm 0.04, n = 5 \) sessions in 2 mice; \( t_{12} = 0.12, P = 0.9 \), two-tailed unpaired \( t \)-test; Figure 6- figure supplement 1B, D). The proportion of active putative pyramidal cells with significant theta modulation was not different between conditions (ØT: 92.8%, \( n = 361 \) active cells; OT: 90.3%, \( n = 155 \) active cells; \( \chi^2 = 0.91, df = 1, P = 0.34 \), Chi-Square test). The coupling of spikes to theta oscillation was also not significantly different between conditions in terms of preferred phase (ØT: 200.26° ± 2.6, \( n = 361 \) active cells; OT: 198.66° ± 4.12, \( n = 155 \) active cells; \( F = 0.08, P = 0.77 \), circular ANOVA; Figure 6-figure supplement 2A, B) and strength (mean resultant vector length ØT: 0.18 ± 0.006, \( n = 361 \) active cells; OT: 0.19 ± 0.009, \( n = 155 \) active cells; \( Z = -1.63, P = 0.1 \), two-tailed WRS test; Figure 6-figure supplement 2A, C).

We then analyzed place cells’ theta phase precession. To compensate for decreased spatial stability in the ØT condition we took into account only trials with good correlation with the average place fields (Spatially Stable Trials or SST) for place cells recorded in the empty track (Schlesiger et al., 2015), but included all trials for place cells recorded in the track with objects. The stability index of SST fields in ØT was not significantly different from the stability index of all fields in OT (ØT, \( n = 52 \) SST fields; OT, \( n = 151 \) fields; \( Z = 0.18, P = 0.86 \), two-tailed WRS test). The percentage of fields with significant (\( P < 0.05 \)) and negative correlation between phase and position (i.e., precessing fields) was high in the track with objects (41.9%), comparable to that observed in real linear tracks in mice but low in the empty track (8%; \( \chi^2 = 15.21, df = 1, P < 10^{-4} \) compared to OT, Chi-Square test). Accordingly, the correlation between phase and position was significantly different from zero for place cells recorded in the track with objects (\( r = -0.18 \pm 0.018, n = 99 \) fields; \( P < 10^{-11} \), one sample sign-test; Fig. 6A and B) but not for those recorded in the track without objects (\( r = 0.03 \pm 0.026, n = 14 \) fields; \( P = 0.42 \), one sample sign-test; Fig. 6A and B). Moreover, phase precession slopes (calculated on normalized place field sizes) were negative and significantly different from 0 for cells recorded in the track with objects (-2.43 ± 0.23 rad/U, \( n = 99 \) fields; \( P < 10^{-11} \), one sample sign-test; Fig. 6C) but not in the track without objects (1.18± 0.50 rad/U, \( n = 14 \) fields; \( P = 0.4 \), one sample sign-test; Fig. 6C).

In the track without objects, the decrease in phase-position correlation could result from the higher inter-trial spatial dispersion, which could lead to spikes at different theta phases for identical positions. To assess this possibility, we performed phase-precession analysis on single-trial-detected fields and averaged the slopes of individual passes (Schmidt
et al., 2009). The correlation was still negative and significantly different from 0 in OT \((r = -0.19 \pm 0.29, n = 92\) single-trial fields; \(t_{91} = -4.53, P < 10^{-4},\) one sample \(t\)-test) but not in \(\emptyset T\) \((r = -0.004 \pm 0.03, n = 35\) single-trial fields; \(t_{34} = -0.92, P = 0.92,\) one sample \(t\)-test). Similarly, the slope of the regression line was negative and significantly different from 0 in OT \((-2.27 \pm 0.56\) rad/U, \(n = 92\) single-trial fields; \(P = 0.004,\) sign-test) but not in \(\emptyset T\) \((0.79 \pm 0.56, n = 35\) single-trial fields; \(P = 0.73,\) sign-test).

Because a low percentage of active cells were place cells in the track without objects, we ran an additional analysis that is independent of place field detection. It exploits the fact that phase precessing cells emit theta paced spikes at a frequency slightly faster than the concurrent LFP theta oscillation (O’Keefe and Recce, 1993). We performed cross-correlation between the power spectra of neuronal spikes and LFP for all active cells with significant theta modulation of spiking activity \((\emptyset T: 117/342\) cells = 34.2%; \(OT: 78/142\) cells = 54.9%; \(\chi^2 = 17.9, df = 1, P < 10^{-4},\) Chi-square test) and compared the frequency shift (>0) between spiking and LFP theta oscillations between the two conditions (Geisler et al., 2007) (Fig. 6D). The shift was significantly higher in the OT \((0.72 \pm 0.05\) Hz, \(n = 78\) active cells. Fig. 6D) versus \(\emptyset T\) \((0.26 \pm 0.01\) Hz, \(n = 117\) active cells; \(Z = -8.73, P < 10^{-17},\) two-tailed WRS test; Fig. 6D). Altogether, these results suggest that local visual cues are important for proper theta phase precession in the hippocampus.

To further investigate the effect of local visual cues on temporal coding we next focused on theta-timescale spike coordination. Previous studies have reported, for place cells with overlapping place fields, a positive correlation between the physical distance separating their place fields’ centers and the time (or phase) lag of their spikes within individual theta cycles (Skaggs et al., 1996; Dragoi and Buzsáki, 2006). Our analysis revealed a strong correlation between theta phase and physical distance in the presence of virtual 3D objects \((OT: R = 0.44, n = 214\) pairs in 2 mice; \(P < 10^{-10},\) Pearson correlation; Fig. 6E, F) but not otherwise \((\emptyset T: R = 0.18, n = 27\) pairs in 3 mice; \(P = 0.38,\) Pearson correlation; Fig. 6E, F). These results show that local visual cues are important for temporal coding in the hippocampus beyond theta phase precession.
Discussion

Our study aimed at determining whether local sensory cues could influence hippocampal spatial coding resolution. We found that local sensory cues could increase spatial coding resolution through an increase in the proportion of spatially selective place cells among active cells but also enhanced place fields’ spatial selectivity and stability. These effects were local within the same environment and dynamic upon cue manipulations. Local sensory cues also proved to be important for temporal place cell coding such as theta phase precession and theta timescale spike coordination.

Spatial resolution can be improved by pooling information across neurons (Wilson and McNaughton, 1993). We found that local visual cues could dramatically increase the number of place cells among active cells (by a 3-fold factor). The mechanisms of place cell activation are not fully understood. Using sensory-based models of place cells activation (Hartley et al., 2000; Strösslin et al., 2005; Barry et al., 2006; Sheynikhovich et al., 2009) one can predict that an increase in the quantity/quality of sensory cues in an environment will enhance the number of place cells coding that environment (Geva-Sagiv et al., 2015). However, previous studies using local enrichment with multimodal sensory cues or real objects reported only weak or no effects on dorsal hippocampal cell activity. One study recording in rats navigating between cue rich and cue poor parts of the same track reported no effect on the proportion of place cells or on the density of place fields (Battaglia, 2004). Furthermore, population vector analysis did not reveal a better disambiguation of nearby locations in the cue rich part of the track compared to the cue poor suggesting similar spatial coding resolution (Battaglia, 2004). Others studies found no overall increase of place cells proportion in 2D environment containing real objects nor a specific bias for place cells to fire near the objects (Renaudineau et al., 2007; Deshmukh and Knierim, 2013). One possibility to explain the lack of recruitment of additional cells in these studies could be a high recruitment rate of the dorsal hippocampus even in the “cue poor” condition due to the presence of uncontrolled local cues (Ravassard et al., 2013).

We found that place field density was specifically increased near objects. However, studies so far have revealed an homogeneous allocation of place fields in space (Muller et al., 1987; Rich et al., 2014) in a given environment. Locally activated place cells could correspond to landmark vector (LV) cells, which tend to discharge unspecifically near several
objects or landmarks in a given environment. However, the proportion of these cells is
generally low in the dorsal hippocampus (between 6-8 %) which is in line with the fact that
places near real objects are not overrepresented at the population level. We note however
that this proportion may vary depending on the recording location along both the proximo-
distal axis and radial axis. For example, the distal part of CA1, closer to the subiculum, is
more heavily innervated by the lateral entorhinal cortex where LV cells were first discovered
(Deshmukh and Knierim, 2011) and which is believed to feed information about the “what”
visual stream to the hippocampus (Knierim et al., 2013). Extracellular recordings specifically
targeting this area in the intermediate hippocampus reported an increased proportion of
place cells in the presence of objects (Burke et al., 2011). Whether virtual objects are
perceived by mice as real objects is unclear. They notably lack the multisensory component
inherent to real objects (Connor and Knierim, 2017). Nevertheless, they triggered a large
(50%) increase in place cell’s proportion which is not compatible with the modest proportion
of LV cells reported in our and previous studies.

Instead, our results are more compatible with the hippocampal mapping system
using local visual cues to improve its spatial coding resolution. Consistent with this
hypothesis, spatial coding was not only quantitatively but also qualitatively increased with a
higher spatial selectivity, spatial information content and stability of place fields. Previous
studies have reported overrepresentations near rewarded location (O’Keefe and Conway,
1978; Hollup et al., 2001; Dupret et al., 2010; Danielson et al., 2016; Sato et al., 2018) or
specific sensory cues (Wiener et al., 1989; Hetherington and Shapiro, 1997; Sato et al.,
2018). Importantly we could also observe overrepresentations of the ends of the maze in ØT,
where rewards are delivered and which are associated with prominent visual cues.

Nevertheless, End-track fields had a low spatial information content and stability when
compared to fields recorded in OT (but similar to On-track fields recorded in the same
maze). This argues against increased spatial coding resolution at these locations and further
suggests a possible dissociation between overrepresentation and increased spatial coding
resolution. Finally, improved coding resolution near objects could be instantaneously tuned
upon object manipulation while overrepresentations of specific sensory stimuli or rewarded
locations usually takes several days to develop (Le Merre et al., 2018; Sato et al., 2018).

A previous study specifically compared place cell coding in real and virtual reality
environments with distal visual cues only in rats (Ravassard et al., 2013). They reported a
lower number of spatially modulated cells and lower spatial selectivity in the virtual environment and concluded that distal visual cues alone are not sufficient to fully engage the hippocampal mapping system. Our results complement this study by showing that local visual cues, on the other hand, can increase the proportion of spatially modulated cells (i.e. place cells) among active cells and spatial selectivity. Several factors could explain the specific effect of local visual cues on spatial coding observed in the present study. First, objects could constitute a stable reference point in space to refine estimation of the current subject’s position possibly through anchoring of the path integrator system (McNaughton et al., 2006; Poucet et al., 2015). Close to the objects, this effect could be further reinforced through motion parallax effect. Second, objects as local visual cues have a higher sensory resolution compared to distal visual cues. This can lead to increased spatial coding resolution according to sensory based models of place cell activation (Hartley et al., 2000; Strösslin et al., 2005; Barry et al., 2006). Accordingly, animals tend to increase their sensory sampling rate in order to get a better sensory resolution near important locations (Geva-Sagiv et al., 2015). Third, objects as salient cues in the environment could modify the attentional state of the animal and favor spatial awareness. Such rise in attention has been shown to increase spatial selectivity in mice (Kentros et al., 2004). However, we note that animals were not required to pay close attention to objects locations to perform the task, as task performance was not different between the ØT and OT conditions. Alternatively, objects could represent a source of additional noise in the system thus requiring a higher number of spatially modulated cells and increased spatial selectivity for efficient position coding. However, position decoding was very poor in the maze without objects, which argues against this possibility.

The effects of local cues on spatial coding accuracy were even more pronounced in the temporal domain. Indeed, in the absence of local cues theta phase precession was strongly reduced as observed in rat running in place on a wheel (Hirase et al., 1999) despite the presence of place fields. When local cues were included, however, hippocampal place cells precessed at a rate comparable to that observed in real environments (Middleton and McHugh, 2016). To ascertain that this effect did not result from changes in place fields’ quality, additional analysis, independent of place fields’ detection, were performed (Geisler et al., 2007). These analyses also showed that in the presence of local cues individual cells’ firing tended to oscillate faster than theta oscillation recorded in the LFP, a sign of theta
phase precession while this was much less the case in the absence of local cues. Importantly, the frequency and power of the theta oscillation recorded in the LFP and the coupling of putative pyramidal cells’ firing to this oscillation were also not significantly different between conditions and cannot explain observed differences. The only difference was an attenuation of theta frequency speed modulation in the absence of local cues while theta amplitude vs speed modulation was equivalent in both conditions. A similar absence of theta frequency vs speed modulation (with intact theta amplitude vs speed modulation) was observed in rats navigating virtual reality environments in the absence of local visual cues (Ravassard et al., 2013). However, in this study, theta phase precession was unaffected. Thus, the link between an absence of theta frequency vs speed modulation and reduced theta phase precession is not straightforward. Future studies are needed to decipher the mechanisms of the effect of local cues on theta phase precession. Theta phase precession is thought to be involved in the generation of theta sequences, where the time lags between spikes of place cells with overlapping place fields are proportional to the distance separating those fields. This so-called theta sequence compression is thought to be important for spatial memory. Here we found that theta timescale coordination could be observed in the presence of 3D objects only. This suggests that local sensory cues are important for temporal coding beyond theta phase precession.

Altogether, our results show enriching an environment with local visual cues allows coding at higher spatial resolution with a high number of spatially modulated cells, smaller firing fields, increased spatial selectivity and stability and good theta phase precession/theta timescale spike coordination. The use of virtual reality raises a growing interest in the field of neuroscience to study spatial cognition in rodents but also in non-human and human primates (Epstein et al., 2017). Our results suggest that enriching these environments with local visual cues could help comparing spatial coding in real and virtual environments.

We observed that local visual cues induce a rescaling of spatial coding which is both global and local. What would be the benefit of this rescaling? In the wild, rodents can travel kilometers away from their home to food locations through empty fields (Taylor, 1978). Mapping all parts of explored environment at high resolution would require a very large number of neurons and computational power (Geva-Sagiv et al., 2015). Accordingly, place fields tend to be larger in bigger environments (Fenton et al., 2008) and the statistics of new place cells recruitment as an environment becomes bigger are non-uniform (Rich et al.,
2014). Thus there might be a computational benefit to be able to map at high resolution important places like home base or food locations and to map at lower resolution long transition routes between those locations (Geva-Sagiv et al., 2015). Such resolution could depend on the number of local sensory information as presented here. Future work should decipher whether increased spatial coding resolution is associated with better navigational accuracy and spatial memory.
Materials and methods

Animals

All experiments were approved by the Institut National de la Santé et de la Recherche Médicale (INSERM) animal care and use committee and authorized by the Ministère de l’Éducation Nationale de l’Enseignement Supérieur et de la Recherche (agreement number 02048.02), in accordance with the European community council directives (2010/63/UE).

Data were acquired from 8 male mice C57BL/6J (Janvier/Charles River) between 8 and 12 weeks during the recording phase (weight: 21 – 23.6 g). The mice were housed 2 or 3 per cages before the first surgery and then individually with 12 inverted light/dark cycles. Trainings and recordings occurred during the dark phase.

Surgical procedure to prepare head fixation

A first surgery was performed to implant a fixation bar later used for head-fixation. Animals were anesthetized with isoflurane (3%) before intraperitoneal injection of ketamine (100 mg/Kg) mixed with xylazine (10 mg/Kg) supplemented with a subcutaneous injection of buprenorphine (0.06 mg/Kg). Two jeweller’s screws were inserted into the skull above the cerebellum to serve as reference and ground. A dental cement hat was then constructed leaving the skull above the hippocampi free to perform the craniotomies later on. The free skull was covered with a layer of agarose 2% (wt/vol) and sealed with silicon elastomer (Kwik-Cast, World Precision Instruments). A small titanium bar (0.65 g; 12 x 6 mm) was inserted in the hat above the cerebellum to serve as a fixation point for a larger head plate used for head fixation only during trainings and recordings.

Virtual reality set up

A commercially available virtual reality system (Phenosys Jetball-TFT) was combined with a custom designed 3D printed concave plastic wheel (center diameter: 12.5 cm; side diameter: 7.5 cm; width: 14 cm, covered with silicon-based white coating) to allow 1D movement with a 1/1 coupling between movement of the mouse on the wheel and movement of its avatar in the virtual reality environment. This solution was preferred to the original spherical treadmill running in a X-only mode (which takes into account only rotations of the ball in the X axis to actualize the position of the avatar in the virtual reality environment) which also
allows 1D movement but with a more variable coupling between movement of the mouse on the treadmill and its avatar in the virtual reality environment. The wheel was surrounded by six 19-inches TFT monitors, which altogether covered a 270 degrees angle. Monitors were elevated so that the mice’s eyes level corresponded to the lower third of the screen height to account for the fact that rodents field of view is biased upward. The head fixation system (Luigs and Neumann) was located behind the animal to not interfere with the display of the virtual reality environment. The virtual reality environment was a virtual 200 cm long and 32 cm wide linear maze with different patterns on the side and end walls and virtual 3D objects (see virtual reality environments section). Movement of the wheel actualized the mouse’s avatar position. The mouse could only perform forward or backward movements but could not turn back in the middle of the track (see training section).

**Virtual reality environments**

*No Object Track (ØT)*

Each side wall had a unique pattern (black and orange stripes on one wall; green crosses on black background on the other wall). End-walls had grey triangular or round shapes on a yellow background (Fig. 1A).

*Object Track (OT)*

This maze was identical to the ØT maze concerning wall patterns and dimensions but 3 virtual objects were included on the sides between the animal trajectory and the walls (Fig. 1A). The objects were a yellow origami crane (dimensions: 9 x 9 x 7 cm; position: 37 cm from end wall), a blue and grey cube (dimensions: 5 x 5 x 5 cm; position: 64 cm from end wall) and a tree (15 x 15 x 22 cm; position: 175 cm from end-wall). The animal could neither orient toward the objects nor get any sensory feedback from them by any other mean but vision.

*Enriched Objects Track (EOT)*

This maze had the same dimensions as previous mazes and included the same virtual reality objects (identical dimensions and locations than in the previous maze) but the side walls had distinct symmetrical patterns in different locations along the maze (50 cm long; black dots on white background, black and green squares, black and white stripes and green crosses on black background). Outside the maze walls, two large 3D columns were positioned on each side (dimensions 8 x 8 x 47 cm; positions 58 and 143 cm from end wall) to provide additional visual cues.
**Training**

Mice were first habituated to the experimentalist through daily handling sessions of 20 min or more that continued throughout the experiment. After a 3 days post-surgery recovery period, mice were water-deprived (1 ml/day, including the quantity of water taken during the training). After 2-3 days of water deprivation, they were progressively trained to run in the virtual reality set up. First, mice were familiarized with running head-fixed on the wheel for water rewards in a black track (screens always black). During these sessions, animals received as a reward sweetened water (5% sucrose) for each 50 centimeters run on the wheel. When animals were comfortable with the setup, they were trained to run in one of three linear virtual tracks (familiar track) assigned randomly. When animals reached the end of the track, a liquid reward delivery tube extended in front of the animal and animal had to lick to get the reward (a 4 µL drop of water of 5% sucrose). Animals were then teleported in the same position but facing the opposite direction of the maze and had to run up to the end of the maze in the opposite direction to get another reward. Animals were initially trained during 15 minutes sessions. Session time was progressively increased to reach 60 minutes. *Ad libidum* water access was restored if the weight of the animal decreased beneath 80% of the pre-surgery weight at any stage during training.

**Recording procedure**

When animals reached a stable behavioral performance (at least 1 reward/minute during 60 minutes), we performed acute recordings using silicon probes (4/8 shanks; A-32/A-64 Buzsaki Probe, Neuronexus). On the day before recording, animals were anesthetized (induction: isoflurane 3%; maintenance: Xylazine/Ketamine 10/100 mg/Kg supplemented with Buprenorphine 0.1 mg/Kg) and a craniotomy was drilled above one hippocampus (centered on a location -2 mm posterior and ± 2.1 mm lateral from bregma). The craniotomy was covered with agarose (2% in physiological saline) then sealed with silicon elastomer (Kwik-Cast, World Precision Instruments). On the day of the recording the backside of the probe’s shanks was covered with a thin layer of a cell labeling red-fluorescent dye (Dil, Life technologies) so that its location (tips of the shanks) could be assessed post-hoc histologically. The silicon probe was then lowered into the brain while the animal was
allowed to walk freely on the wheel with the screens displaying a black background. The good positioning of the probe with recording sites in the CA1 pyramidal cell layer was verified by the presence of multiple units showing complex spike bursts on several recordings sites and the recording of sharp-wave ripples during quiet behavior. After positioning of the silicon probe the virtual reality environment was displayed on the screen. All mice \((n = 8)\) experienced first the familiar environment (either \(\varnothing\)T, OT or EOT) for around 20 back and forth trials. For mice trained in \(\varnothing\)T or OT \((n = 3\) and 2, respectively), this first exploration was followed, after 3 minutes of free running with the screens displaying a black background, by exploration of a new environment, identical to the previous one except for the presence of the three 3D objects (objects were added for mice trained in \(\varnothing\)T and removed for mice trained in OT) for another 20 consecutive back and forth trials. For some of these mice \((n = 2\) for EOT, \(n = 1\) for OT and \(n = 2\) for \(\varnothing\)T) sessions in the familiar track and novel track were divided into two sub-sessions interleaved by 3 min of free running with the screens black. The two sub-sessions in the familiar environment and the new environment were pulled together for analysis. Note that animals stayed head-fixed on the wheel surrounded by screens during the entire recording session.

**Data Acquisition and Pre-Processing**

The position of the animal in the virtual maze was digitalized by the virtual reality controlling computer (Phenosys) and then sent to a digital-analog card (0-4.5V, National Instrument Board NI USB-6008) connected to the external board (I/O Board, Open Ephys) of a 256 channels acquisition board (Open Ephys). Neurophysiological signals were acquired continuously on a 256-channels recording system (Open Ephys, Intan Technologies, RHD2132 amplifier board with RHD2000 USB interface board) at 25,000 Hz. Spike sorting was performed semi-automatically using KlustaKwik (Rossant et al., 2016); [https://github.com/klusta-team/klustakwik](https://github.com/klusta-team/klustakwik). Clusters were then manually refined using cluster quality assessment, auto- and cross-correlograms, clusters waveforms and similarity matrix (Klustaviewa(Rossant et al., 2016)).

**Data Analysis**
All subsequent analyses were conducted using custom-developed softwares written in MATLAB (MathWorks).

**Reward & Object Zones Definition**

The reward zones, located between the maze extremities and 10% of the track length (0-20 cm and 180-200 cm), were not considered in the analysis. The object zone was composed of two zones, one from 30 to 70 cm including both the origami crane and the cube and the other from 160 to 180 cm including the tree.

**Firing Rate Map**

The maze was divided into 100 spatial bins measuring 2 cm. For each trial, the number of spikes and the occupancy time of the animal in each spatial bin were calculated to obtain the spikes number vector and the occupancy time vector, respectively. These vectors were smoothed using a Gaussian filter with a half-width set to 10 spatial bins. Spikes occurring during epochs when velocity was lower than 2 cm/s were removed from all analysis. The smoothed spikes number vector was divided by the smoothed occupancy time vector to obtain the firing rate vector for each trial. The firing rate vectors were pooled for a specific condition (e.g., Familiar Objects Track) and direction of the animal (e.g., back) to generate a firing rate map. These pooled vectors were also averaged to provide the mean firing rate vector, corresponding to the mean firing rate for each spatial bin.

**Pyramidal Cell Classification**

Cells with a mean firing rate lower than 20 Hz and either a burst index (Royer et al., 2012) greater than 0 or the spike duration greater than 0.4 ms were classified as putative pyramidal neurons. They were classified as interneurons otherwise.

**Active Cells Classification**

A cell was considered as active when the mean firing rate was greater than 0.5 Hz, the peak firing rate was greater than 1.5 Hz and the cell fired at least one spike in 50% of the trials. These 3 criteria had to be verified in either the forth or back direction.

**Place Fields Detection**

To detect a mean place field, a bootstrap procedure was performed. For each trial, a new spikes train was generated using a Poisson process with $\lambda$ equal to the mean firing rate of the trial and a 1 ms time interval. A “randomized” firing rate map was then generated and the mean firing rate vector was determined and compared with the mean firing rate vector from the initial rate map. This operation was repeated 1000 times to determine a $P$-value.
vector (P-value for each 2 cm spatial bin). Place fields candidates were defined as a set of more than 3 continuous spatial bins associated with P-values lower than 0.01. Two place fields were merged when the distance between their closest edges was at most equal to 5 spatial bins (10 cm). Place fields’ edges were extended by at most 5 spatial bins (for each edge) when the P-value was below 0.30 for these bins. A field with a size greater than 45 spatial bins (90 cm) was not considered as a place field. To validate a mean place field, the cell had to verify a stability criterion. Spatial correlations were calculated between the firing rate vector of each trial and the mean firing rate vector. The spatial bins corresponding to other detected place fields were not considered in the spatial correlations. The place field was validated if the spatial correlations were greater than 0.60 for at least 40% of trials. Unless specified, when several mean place fields were detected, only the place field with the highest peak was conserved. An active cell with at least one place field in one direction was considered as a place cell.

The same procedure was applied to detect place fields per lap without the stability criterion, which cannot be calculated on single trials. A place field per lap was conserved if it overlapped at least 1 spatial bin with the closest mean place field.

**Stability Index**

The stability index of a cell was computed as the mean of the spatial correlations between all pairs of firing rate vectors. This way, the cell stability index takes into account the activity patterns from all the trials and provides a reliable quantification of the inter-trial reproducibility of the cells activity. Note that this stability index is different from usual stability indexes based on correlations of mean firing rates between even and odd trials or two halves of the same recording session thus values obtained cannot be directly compared.

**Spatial Information**

The spatial information (SI) was calculated according to the following formula (Skaggs et al., 1996):

\[
SI = \sum_{i=1}^{N} \left( \frac{FR_i}{FR} \times \frac{OT_i}{OT_T} \times \log_2 \left( \frac{FR_i}{FR} \right) \right)
\]

where N is the number of spatial bins (N = 100), \( FR_i \) is the mean firing rate determined in the i-th spatial bin, \( FR \) is the mean firing rate, \( OT_i \) is the mean occupancy time determined in the i-th spatial bin, \( OT_T \) is the total occupancy time based on the mean occupancy time vector.
As another measure of spatial information, we computed the Mutual Information using the following formula:

$$MI = \sum_{i=1}^{N} \sum_{j=1}^{4} p_{i,j} \log \left( \frac{p_{i,j}}{p_i \cdot p_j} \right)$$

Where $N$ is the total number of spatial bins, $p_i$ is the occupancy probability of the animal in the $i$-th spatial bin, $p_j$ is the probability to obtain a firing rate amongst one of 4 non-overlapping quartiles of firing rates and $p_{i,j}$ is the joint probability of the animal to be in the $i$-th spatial bin with a firing rate in the $j$-th quartile. The Mutual Information was then normalized with a surrogate based distribution to correct possible bias due to basal firing rate (Souza et al., 2018).

**Out/In Field Firing Ratio**

The out/in field firing ratio was computed as the ratio between the mean firing rate outside the mean place field (excluding secondary place fields) and the mean firing rate inside the mean place field.

**Place Field Dispersion**

A place field dispersion measure has been computed to quantify how much each place field per lap was dispersed around the mean place field. The place field dispersion (PFD) was calculated according to the following formula:

$$PFD = \frac{L}{N} \left[ \frac{1}{M} \sum_{i=1}^{M} (C - C_i)^2 \right]^{\frac{1}{2}}$$

where $C$ is the center of the mean place field, $C_i$ is the center of the field in the $i$-th lap and $M$ is the number of laps with a single-trial detected field, $L$ is the total length of the maze and $N$ is the number of spatial bins. The center of a place field was defined as the spatial bin with the highest firing rate.

**Place Field Width**

Place field width was computed as the distance between the place field edges and only determined for entire place fields. A place field was considered as complete when its firing rate increased above 30% of the difference between highest and lowest place field activity and then dropped below this threshold.

**On-Track and End-Track Fields**
A mean place field was considered as End-Track field if the peak of the field was located at the beginning of the reward zone (i.e., at the 11-th or the 90-th spatial bin). All other fields were classified as On-Track fields.

**Distribution of place fields’ position**

To statistically assess whether the place fields were non-uniformly distributed in the maze, we tested the null hypothesis that all fields were uniformly distributed. Based on this hypothesis, the total number of place fields was redistributed with an equal probability to be in each 10-cm spatial bin. The standard deviation of this uniform distribution was then compared to the initial distribution. This operation was repeated 1000 times (bootstrap procedure) to obtain a P-value, corresponding to the probability of the place fields to be uniformly distributed. When this P-value was lower than 0.05, the null hypothesis was rejected and the distribution was considered as non-uniform. To ensure that single values of place fields’ percentage in a given bin did not make the distribution non-uniform, values greater than the 93-th percentile and lower than the 6-th percentile have been excluded from the initial distribution.

**Local Stability**

A local stability index was developed to assess how consistent a firing rate was over the laps for a given spatial bin. To this end, two mean firing rate vectors were calculated, in the neighborhood of each spatial bin (2-spatial bins half-window) for even and odd trials. Local stability index was defined as the spatial correlation between these two vectors for a given spatial bin.

**Position Decoding**

To address how informative the firing rates of the CA1 pyramidal cells ensemble were about the position of the animal in the different virtual environments, we used Bayesian decoding and Firing Rate Vectors (FRV) methods. For each time window, the distribution of the animal position probability across the whole maze was calculated using the firing activity of all active cells (place cells and non place cells). The mode of this distribution (maximum of probability) was chosen as the decoded position for a given time window. We used a classical “memoryless” Bayesian decoder (Brown et al., 1998; Zhang et al., 1998). The decoding of the spikes data was restricted to periods when the animal was running (speed > 2 cm/s) or with good Theta/Delta ratio and cross-validated using the “leave one out”
approach. We computed the animal’s probability to be in each spatial bin \( x \) (2 cm) knowing that \( N \) cells fired \( n \) spikes in a time window according to the following formula:

\[
P(x | n) = C(\tau, n)P(x) \left( \prod_{i=1}^{N} f_i(x)^{n_i} \right) \exp \left( -\tau \sum_{i=1}^{N} f_i(x) \right)
\]

with \( P(x) \) a uniform spatial prior, \( f_i(x) \) the average firing rate of the neuron \( i \) over \( x \) (i.e., the tuning curve over the position), \( n_i \) the number of spikes emitted by the neuron \( i \) in the current time window and \( \tau \) the length of the time window (150 ms; non-overlapping) and \( C(\tau, n) \) a normalization factor intended to set the posterior probability for one time window to 1. This formula assumes that the spikes trains obey to a Poisson process and that cells activity is independent. Position decoding was also preformed using the FRV method (Middleton and McHugh, 2016). For each 100 ms time bin, the Pearson correlations were calculated between firing rates across all cells and the mean firing rates from all cells for a given spatial bin. A decoding error was defined as the absolute value of the difference between decoded and real position. Accuracy was defined as the probability at the real position in a particular time bin. To ensure that the position decoding was not influenced by the number of cells, a drop cell approach was performed (van der Meer et al., 2010). Briefly, for \( M \) recorded active cells, the position was decoded using \( k \) different subsets of cells with increasing sizes \( 5*k \) with \( k \) ranging from 1 to the last multiple of 5 < \( M \). For the \( k \)-th subset, the decoding was repeated 50 times using \( 5*k \) randomly selected cells and the median value of probabilities for a given time and spatial bin was chosen as the final probability. The presented results were computed for a subset composed of 20 cells (\( k = 4 \)).

**Map Similarity over Trials**

To analyze the dynamic of the changes of spatial representation between familiar and novel conditions, map similarities were performed for 10 back and forth trials before and after the experimental manipulation. For each active putative pyramidal cell, map similarities consisted of the Pearson correlation between the firing rate map of each back and forth trial and a template firing rate map. This template firing rate map was calculated as the average of the firing rate map from all the laps in the condition with objects (most stable condition). The maps corresponding to back (forth) trials were correlated to the mean back (forth) trial map in the object condition and the correlations values were averaged to obtain a single value for this back and forth trial. When map similarity was determined for a lap in the object condition, the template firing rate map was computed without it.
**Landmark Vector cells detection**

For this analysis, we defined individual objects zones (IOZ) for each object. For a given object, IOZ corresponded to all spatial bins occupied by the object plus an additional margin of 7 spatial bins (14 cm), which was always located before the object in the animals’ movement reference frame to take into account the anticipatory nature of some LV cells (Geiller et al., 2017). Thus IOZ for each object were different for back and forth directions.

Here are the IOZ defined for each object in both directions: origami crane: 20-42 cm and 32-56 cm, cube: 46-68 cm and 60-82 cm and tree 154-180 cm and 166-180 cm. A cell was classified as LV cell if at least one of its place fields was in the same IOZ for both directions (note that secondary mean place fields were included in this analysis).

**Phase precession Analysis**

Phase precession was calculated on all spikes (above speed threshold) for the track with objects but restrained to Spatially Stable Trials (SST) in the no object condition to equalize stability between both conditions. SST consisted of at least 3 trials where the in-field correlation with the mean place field exceeded 0.6. To assess theta phase precession, the Local Field Potential (LFP) of the channel with the highest number of pyramidal cells (Skaggs et al., 1996) was filtered (4th order Chebyshev filter type II) in the theta band (4-12Hz). The instantaneous theta phase for each time bin (1 ms) was determined using the Hilbert transform of the filtered LFP and a phase was attributed to each spike. Only theta phase locked cells were considered in the following analysis (non-uniform phase distribution, $P < 0.05$, Rayleigh test). Circular linear analysis was used to determine the correlation strength and slope value of the relation between spikes phases and normalized positions (0-1) through the mean place field (Kempter et al., 2012). Briefly, the phase precession slope was computed with a linear regression model between circular (spike phases) and linear (animal’s position) data. The slope of the regression was used to scale the animal’s position and to transform it into a circular variable. A circular-circular correlation could thus be computed on the data to assess the strength of the relationship between spike phases and animal’s position. A significance value was determined by re-computing the correlation values for 1000 permutations of the spikes position.

Analysis of phase precession on single-trial detected fields was also performed (Schmidt et al., 2009). Phase precession slope and correlation values were computed similarly to the previously described method. The single lap slope and correlation values were averaged.
only for sessions with at least 3 significantly precessing trials where the cell emitted a minimum of 4 spikes inside the mean place field.

**Unit-LFP shift and Spike Phase Spectrum**

To quantify phase precession independently of the position of the animal and the place field detection, Unit-LFP shift was used. For all active putative pyramidal cells, a discreet multitaper spectrum in the theta band (4-12Hz) of the cell’s spikes was performed (mtpoint spectrum, Chronux) as well as the continuous multitaper spectrum of the simultaneously recorded LFP (mtspectrumpc, Chronux). A theta modulation index (Mizuseki et al., 2009) was defined for each cell spike spectrum as the mean power around the peak theta frequency ± 0.5 Hz divided by the mean power below 5Hz or above 9Hz. A cell was considered as theta modulated if this index was greater than 1.4. The cross correlogram was then calculated for theta modulated cells to determine the lag in the theta band between the LFP and the cells’ spectrum (Geisler et al., 2007). A positive lag indicates that the cell is firing faster than the concurrent LFP.

**Speed modulation of theta frequency and Amplitude**

The instantaneous theta frequency was computed from the instantaneous theta phase extracted from the Hilbert transform of the filtered LFP in the theta band. For each time \( t_i \), the instantaneous theta frequency \( F_\theta(t_i) \) was determined based on the unwrapped phase:

\[
F_\theta(t_i) = \frac{\text{Phase}(t_{i+1}) - \text{Phase}(t_i)}{2\pi \times F_s}
\]

where \( F_s \) is the sampling frequency.

Instantaneous theta amplitude was defined as the module of the LFP Hilbert transform and normalized by the mean LFP theta amplitude. The Pearson correlation coefficient was then calculated between the speed of the animal and theta frequency/amplitude.

A theta peak detection method was also used to calculate the instantaneous theta frequency. Theta peaks were detected with zero crossing of the instantaneous LFP phase and frequency was deduced from the time between two successive theta peaks. This value was affected to all the time stamp of the corresponding cycle.

**Theta timescale correlation**

To calculate the theta timescale lag between the spikes of two overlapping place fields, two cross-correlograms (CCGs) were computed (Skaggs et al., 1996; Dragoi and Buzsáki, 2006; Robbe and Buzsaki, 2009). First a “Real time-scale” CCG was computed with a 1 s time.
window and 3 ms time bin. The CCG time lag was defined as the peak of the filtered CCG between [0-2] Hz. “Theta time-scale” CCG was computed with a 200 ms time window and 1 ms time bin. The theta time lag was defined as the peak of the filtered CCG between [0-20] Hz. Only pairs of cells with a CCG mean bin count of 1 count/ms were included in this analysis. The relation between the CCG time lag and theta time lag was assessed using Pearson correlation.

**Preferred Theta Phase**

Preferred theta phase and Mean Resultant Vector Length of each cell were defined thanks to circ_mean and circ_r circular statistics Matlab toolbox functions (Berens, 2009). Global phase 180° was defined as the maximal pyramidal cells activity (Skaggs et al., 1996).

**Code availability**

All custom written codes used in the present study are available upon reasonable request.

**Statistics**

All statistical analyses were conducted using Matlab codes (MathWorks). For each distribution, a Lilliefors goodness-of-fit test was used to verify if the data were normally distributed and a Levene test was used to assess for equal variance. If normality or equal variance were not verified, we used the Wilcoxon rank sum test otherwise the Student t-test was used to compare two distributions. In case of multiple comparisons, the Kruskal-Wallis test with Bonferroni post-hoc test was used. Spatial correlations were computed using Pearson’s correlation coefficient. Chi-square test was used to compare percentages of phase precessing cells. For circular distributions comparison, we first tested if they came from a Von-Mises distributions (Watson Test) with a common concentration (circ_ktest), if the distribution respected these constrains circular ANOVA: Watson-Williams multi-sample test for equal means (circ_wwtest) was applied.

**Data availability**

Data acquired in the present work are stored on INMED server and available upon reasonable request.

Figure 1 - figure supplement 1: Histology and spike sorting

A. Representative histology slide showing a silicon probe track ending in CA1 pyramidal layer. Scale bar: 1mm. B. (Right) Auto-correlograms (red) and cross-correlograms (black) of 20 CA1 units recorded simultaneously. (Left) Average units waveforms (for visualization each row is normalized by the unit maximum average waveform).
Figure 6 - figure supplement 1: Speed modulation of LFP theta frequency and amplitude in OT and ØT

A-B. Mean theta frequency (A) or amplitude (B) across all recording sessions as a function of animal speed (bin: 5 cm/s). C-D. Box plots of the correlation between theta frequency (C; \( P = 0.01 \), two-tailed unpaired t-test) or amplitude (D; \( P = 0.9 \), two-tailed unpaired t-test) vs speed for individual sessions.
Figure 6 - figure supplement 2: Theta modulation of spikes in OT and ØT

A. Mean theta phase plotted against strength of phase locking (Mean Resultant Vector Length: MRLV) for all theta modulated cells (P < 0.05, Rayleigh Test) in OT (orange) and ØT (blue). Solid lines: probability distribution of the preferred theta phase for the two conditions. Black line: illustrative theta cycle. B. Box plots of the mean theta phase for OT (orange) and ØT (blue) conditions (P = 0.77, F = 0.08, circular ANOVA). C. Box plots of the Mean Resultant Vector Length in OT (orange) and ØT (blue) conditions (P = 0.1, two-tailed WRS test).
