ABSTRACT

FS Tau B is one of the few T Tauri stars that possess a jet and a counterjet as well as an optically visible cavity wall. We obtained images and spectra of its jet-cavity system in the near-infrared H and K bands using the Subaru/Infrared Camera and Spectrograph and detected the jet and the counterjet in the [Fe ii] 1.644 μm line for the first time. Within 2" the blueshifted jet is brighter, whereas beyond ~5" the redshifted counterjet dominates the [Fe ii] emission. The innermost blueshifted knot is spectrally resolved to have a line width of ~110 km s^{-1}, while the innermost redshifted knot appears spectrally unresolved. The velocity ratio of the jet to the counterjet is ~1.34, which suggests that FS Tau B is driving an asymmetric jet, similar to those found in several T Tauri stars. Combining with optical observations in the literature, we showed that the blueshifted jet has a lower density and higher excitation than the redshifted counterjet. We suggest that the asymmetry in brightness and velocity is the manifestation of a bipolar outflow driving at different mass-loss rates, while maintaining balance of linear momentum. A full explanation of the asymmetry in the FS Tau B system awaits detailed modeling and further investigation of the kinematic structure of the wind-associated cavity walls.

1. INTRODUCTION

Recent observational progress in the study of jets and outflows from low-mass young stellar objects (YSOs) has focused on revealing how outflows are driven from close to the star and its inner disk. In the stage of T Tauri stars (TTSs), the YSOs have exposed their central stars and the close vicinity in the optical wavelengths. The TTSs are known to drive jets in optical forbidden emission lines. High spatial resolution spectra obtained from the Space Telescope Imaging Spectrograph (STIS) on the Hubble Space Telescope (HST) have provided detailed spatial and velocity distributions of emission lines along and across the jets. Information on physical conditions of several jets within hundreds of AU from the driving region has been extracted from atomic lines such as [O i], [S ii], and [N ii] (Bacciotti et al. 2000; Woitas et al. 2002b; Hartigan & Morse 2007; Coffey et al. 2008; Melnikov et al. 2009).

The [Fe ii] 1.644 μm emission line provides diagnostics probing deeper into the driving source. [Fe ii] traces shocks as do optical forbidden emission lines but suffers less from circumstellar extinction (Hollenbach & McKee 1989). It has been shown from HST/NICMOS images that [Fe ii] traces shocked Herbig-Haro objects close to the more embedded Class I sources (see the discussion in Reipurth et al. 2000). Long-slit near-infrared spectroscopy has shown that kinematic properties of the [Fe ii] line are similar to those seen in the optical [S ii] line and are important to both Class I and II (TTSs) sources (Davis et al. 2003). High-dispersion echelle spectrographs aided with adaptive optics provide spatially resolved [Fe ii] spectra down to scale of 15 AU from the source. The properties of the line profiles along the jet enable opportunities for confrontation with models (Pyo et al. 2003, 2006; Hartigan & Hillenbrand 2009).

Attention has been drawn to the studies of differences in physical properties between the jet and the counterjet of several TTS systems in which both sides of the bipolar jet were detected. Hirth et al. (1994) conducted a long-slit optical spectroscopic survey of TTS jets and found that in 8 out of 15 sources the velocity ratios between the faster side and the slower side of the jet range from 1.4 to 2.6, while in other cases the velocity differences are less significant. Besides asymmetric velocity, forbidden line ratios that trace electron density and temperature also differ between the two sides of jet (Hirth et al. 1997). The jet from RW Aur A is one of the examples that have been extensively studied. It is fainter but faster on the blueshifted side in counterpart to the brighter redshifted side (Pyo et al. 2002b; Melnikov et al. 2009). HST and ground-based telescopes aided with adaptive optics spatially resolved the jet and showed that the non-unity velocity ratio between the counterjet and the jet can be traced in to 0.7 from the driving source in both the optical and near-infrared spectra (Woitas et al. 2002b; Melnikov et al. 2009; Pyo et al. 2006; Hartigan & Hillenbrand 2009). Line ratio diagnostics show that physical conditions inside the jet and the counterjet differ greatly, and the ionization fraction differs by at least a factor of two (Melnikov et al. 2009; Liu & Shang 2012). Understanding the origin of asymmetry close to the driving source would illuminate how mass is loaded onto the outflow driven by a magnetocentrifugal wind.

FS Tau B (Haro 6-5 B) offers another opportunity to examine the asymmetries in an outflow system. It drives a bipolar

* Based on data collected at the Subaru Telescope, which is operated by the National Astronomical Observatory of Japan,
jet along the position angle of $\sim$54$^\circ$, in which the most prominent knot, known as HH 157, lies $\sim$30$''$ from the driving source (Mundt et al. 1984; Eislöffel & Mundt 1998). The asymmetries between the jet and counterjet can be seen in various aspects. Ground-based imaging showed that the jet appears broader and extends longer than the more compact and straight counterjet (Mundt et al. 1991; Eislöffel & Mundt 1998). HST/WFPC2 broadband imaging showed that the jet appears somewhat meandering and more diffuse than the counterjet (Krist et al. 1998). From optical narrowband imaging, the jet appears more prominent in Hα than in [S ii], while the opposite is true for the counterjet. This phenomenon can be seen from both ground-based imaging (Eislöffel & Mundt 1998) and HST/WFPC2 images (Woitas et al. 2002a). Optical long-slit spectra show an asymmetry in velocity (Mundt et al. 1987), with a blueshifted jet $\sim$20% faster than the counterjet if systemic velocity is considered (Eislöffel & Mundt 1998). Although the velocity ratio of 1.2 leads Hirth et al. (1994) to categorize FS Tau B into the rather symmetric half of the sample, the difference observed in the narrowband imaging suggests different physical conditions prevail on the two sides of the jet. We investigate this aspect of asymmetry in the near-infrared wavelengths using the [Fe ii] 1.644 $\mu$m line. An ovoid structure surrounding the northeastern jet shows a polarization pattern centered at FS Tau B (Gledhill & Scarrott 1989) which may either be the outline of a light cone (Krist et al. 1998) or the cavity wall carved by the FS Tau B outflow (Eislöffel & Mundt 1998). Deep imaging by Eislöffel & Mundt (1998) and Krist et al. (1998) revealed its much fainter southwestern counterpart. The asymmetry in the jet and in the ovoid structure related to the outflow cavity wall makes the FS Tau B system a testbed for studying the asymmetry in outflows from young stellar systems.

Although the asymmetry between the jet and the counterjet has been well documented, the origin of asymmetry was not fully understood. Mundt et al. (1987) were inclined to attribute the asymmetry to different density distributions in the surrounding molecular clouds on the two sides of the jet. Considering the difference in initial opening of the jet and the counterjet, Mundt et al. (1991) acknowledged that the difference cannot be explained by differential extinction on the two sides. They concluded that apart from any intrinsic asymmetry, the circumstellar environment plays a fundamental role in shaping the outflow through interaction. The conclusion was based on the observation that the densest gas is often offset from the stellar core in the dark cloud, yet how the dense gas is distributed around FS Tau B is still not clear. To explain the difference in the brightness of the ovoid structures, Krist et al. (1998) proposed that a dark cloud within the northeastern lobe provides denser material for scattering. Overall, interpretations in the literature have mainly focused on possible environmental differences rather than on whether FS Tau B may be driving an intrinsically asymmetric jet and outflow. Using near-infrared imaging and spectroscopy in [Fe ii], we study the properties of the jet close to the driving source. By comparing the near-infrared and optical results, we show that those asymmetric properties of the FS Tau B system may be attributed to an asymmetric outflow driven from the source.

The X-wind model provides a good framework for understanding the morphology and kinematic features for jets and outflows from YSOs (Shu et al. 1994a, 1994b; Shang et al. 1998, 2002). The model describes a wide-angle magnetocentrifugal wind that is driven from the inner edge of a circumstellar disk. The density in the wind is magnetically collimated toward the axis and collisionallyexcites optical lines such as [O i] and [S ii] that appear as the high-speed jet revealed in TTS phase (Shang et al. 1998). The wide-angle nature of the wind is manifested by a very broad line shape excited close to the driving source (Shang et al. 1998, 2010). To compare the observation with the model, obtaining spatially resolved spectra close to the source is crucial.

In this paper, we report results from [Fe ii] 1.644 $\mu$m spectroimaging of FS Tau B with the Subaru Telescope. In Section 2, we summarize the observations, and in Section 3, we show results of the spatially and spectrally resolved [Fe ii] jet. We discuss asymmetric properties of the jet and compare our near-infrared results with those obtained in optical wavelengths from literature in Section 4. We summarize our findings in Section 5.

2. OBSERVATIONS AND DATA REDUCTION

2.1. Subaru IRCS Imaging in H and K Bands

Images of FS Tau A/B were obtained on 2007 January 3, with the Infrared Camera and Spectrograph (IRCS; Kobayashi et al. 2000; Tokunaga et al. 1998) on the Subaru Telescope. Narrowband filters were used to isolate [Fe ii] (with central wavelength $\lambda_c = 1.644 \mu$m and bandwidth $\Delta \lambda = 0.026 \mu$m) and H$_2$ ($\lambda_c = 2.122 \mu$m; $\Delta \lambda = 0.032 \mu$m); broadband H ([$\lambda_c = 1.63 \mu$m; $\Delta \lambda = 0.30 \mu$m]) and K$'$ ($\lambda_c = 2.12 \mu$m; $\Delta \lambda = 0.35 \mu$m ) filters were used to measure the continuum fluxes. The 52.42 mas pixel$^{-1}$ scale yields a 53′.68 square field of view that covers the driving region of HH 157. The telescope was nodded between the source and the sky 3′ southeast from the source. At each nodding position, the pointing was dithered in a five-point square dither pattern (S5) with dithering distance 5′.6. The seeing on the summit of Mauna Kea was between 0′′8 and 1′.1. The total on-source integration times for the H and K$'$ filters were 90 and 162 s, and 900 and 1980 s, respectively, for the [Fe ii] and H$_2$ filters.

We reduced the data with standard procedures, including flat-fielding, bad pixel correction, sky subtraction, ghost identification and replacement, dithered frame shifting, and image stacking. Latency and ghosts caused by the bright FS Tau A were removed from both sky and source frames and replaced with unaffected patches by inspection. The ghost-free sky frames were then combined to obtain the final sky frame, which was subtracted from each ghost-free on-source frame. The reduced on-source frames were shifted and co-added to form the final images.

2.2. IRCS Echelle Spectra with [Fe ii] 1.644 $\mu$m Line

IRCS echelle spectra of FS Tau B in the H band were taken on 2002 November 27. The 0′618 wide $\times$ 5′79 long slit was placed along the jet at the position angle of 55′. The velocity resolution is 60 km s$^{-1}$ ($R \sim 5000$). The plate scales for spatial and dispersion axes are 0′′06 and 0.4044 Å, respectively. The total on-source exposure time was 1200 s. The sky spectra were obtained at positions $\sim$15′ northwest and southwest from the source position. The seeing at the K band was 0′′55.

The spectra were reduced using standard IRAF packages for echelle spectra reduction, following the procedure in Pyo et al. (2003). HR 1570 (A0V, $H = 4.517$) was used as telluric and flux calibration standard. The continuum in the 34th order of the H$\alpha$ line was determined from the sky, and the spectrum was corrected to standard $V$ by dividing the continuum by the flux.

IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy (AURA) under cooperative agreement with the National Science Foundation.
3. RESULTS

3.1. Collimated [Fe II] Counterjet from FS Tau B

Figure 1 shows the Subaru/IRCS images in the (a) [Fe II] and (b) H₂ (1–0) filters. The H₂ images, FS Tau A and the reflection nebulae associated with FS Tau B (R1, R2, and R3) are labeled. Each panel has a field of view of 53.7'7 × 53.7'7 and (0,0) is set at the peak position of R3. The figures were convolved with a Gaussian of 0.52 FWHM for presentation purpose. The intensities are displayed with logarithmic scale. The central 1'' of FS Tau A peak position has been blocked due to saturation. The root-mean-square noise (σ) was determined on each image and contours are superimposed as 3σ, 6σ, 9σ (red), 15σ, 45σ, 75σ, 105σ (green), and 2i×250σ, where i = 0,⋯,10 (cyan). In the [Fe II] image, the position angle of HH 157 (∼55°) is indicated. (c) The [Fe II] counterjet after continuum subtraction, which is the zoomed-in view of the black rectangle shown in (a).

We detected [Fe II] emission associated with the counterjet of FS Tau B. By comparing IRCS images in different filters, we found that an elongated structure appears only in the [Fe II] frame (Figure 1(a)) ∼5'' southwest to R3, at a position angle of 235°. This direct image of the [Fe II] counterjet confirms the faint detection in the HST/NICMOS broadband imaging suggested in Padgett et al. (1999). The emission is unresolved in the transverse direction. No [Fe II] emission was detected beyond R2. On the other hand, following the position angle of 55°, only a faint structure appears at ∼30'' northwest from FS Tau B, close to the position of HH 157. The peak brightness of this knot is ∼5 times fainter than that of the counterjet knot, and its total flux is ∼7 times lower than that of the counterjet.

We subtracted the scaled H-band image from the [Fe II] image to obtain the pure line emission map for the counterjet of FS Tau B, as shown in Figure 1(c). The brighter knot, which peaks 5'' from R3, is the most obvious structure of the counterjet shown in Figure 1(a). Continuum subtraction reveals another more diffuse knot at ∼8.5'', close to the projected position of R2.

We compare our [Fe II] image taken in 2007 January with the [S II] images taken in 1990 November (Eislöffel & Mundt 1998) and in 1997 August (Woitas et al. 2002a) to identify the knots. Eislöffel & Mundt (1998) identified three knots (D, E, and F) in the counterjet while Woitas et al. (2002a) detected only two knots, which we label as W02-C1 and W02-C2, respectively. We apply proper motions of the three knots (Eislöffel & Mundt 1998) to the two images in the later epochs. The brighter [Fe II] knot can be identified with W02-C1 and with knot D if the mean proper motion is ∼0.235 yr⁻¹, comparable to the average proper motion in the counterjet. The much smaller proper motion Eislöffel & Mundt (1998) reported for knot D could have been influenced by the proximity to the driving source. If the fainter
[Fe II] knot has the proper motion of knot E, then it can be identified with W02-C2. Knot F was not detected in Woitas et al. (2002a) and is outside our field of view. We refer to the two [Fe II] knots in the counterjet as D' (for its newly derived proper motion) and E, respectively. In the fainter blueshifted jet, only knot A can be identified if an average proper motion of \( \sim 0.42 \) yr\(^{-1} \) is adopted (Eislöffel & Mundt 1998). Knot B is not detected in either the [S II] image (Woitas et al. 2002a) or in our [Fe II] image. The results of knot identification are summarized in Table 1.

### 3.2. Kinematics of FS Tau B Jet in [Fe II] Line

Figure 2 shows the position–velocity (P–V) diagram of the FS Tau B jet and counterjet obtained from the continuum-subtracted spectra of [Fe II]. The positions are shown relative to R3, which was determined from the continuum peak. The approximate position of FS Tau B, which is invisible in the H band, is at \(-0\farcs8\) (Eislöffel & Mundt 1998). The emission northeast of FS Tau B is the blueshifted jet and the southwestern emission is the redshifted counterjet.

Within 2\" from the driving source, the blueshifted jet appears brighter than the redshifted counterjet in [Fe II] line emission. The flux of the brightest knot at the blueshifted and redshifted sides is \( 2.3 \times 10^{-18} \) and \( 0.63 \times 10^{-18} \) W m\(^{-2} \), respectively. This is counter to the larger scale (\( \sim 5\)') behavior as seen in the narrowband [Fe II] image (Figure 1(a)). The brightest blueshifted knot is around \( 0\farcs15 \) northeast to the fitted position of R3 nebula. The peak positions of the brightest red and blue knots are \( 0\farcs86 \) and \( 0\farcs95 \) from the source, respectively. The emission becomes faint and noisy as the knots extend \( \sim 1\) further away from the peak positions.

The P–V diagram shows that the velocities of the jet and the counterjet of FS Tau B are different. With respect to the systemic velocity, the average velocity for the blueshifted knot is at \(-74.6 \) km s\(^{-1} \), and the redshifted one is at \(+55.8 \) km s\(^{-1} \), with an uncertainty of \( \sim 2 \) km s\(^{-1} \). This gives a radial velocity ratio of \( 1.34 \pm 0.05 \) between the blueshifted and redshifted sides. The brightest blueshifted knot and its extension exhibit large line widths, with an average of \( \sim 110 \) km s\(^{-1} \). It decreases down to \( 80 \) km s\(^{-1} \) further away as the knot intensity decreases. On the other hand, the counterjet is not spectrally resolved with a velocity width \( \lesssim 50 \) km s\(^{-1} \). The residual of OH airglow subtraction at \( V_{LSR} = 0–50 \) km s\(^{-1} \) makes it difficult to investigate kinematics in this flow component.

### 4. DISCUSSION

The combined [Fe II] image and spectra of FS Tau B suggests that it is driving an asymmetric jet. The kinematic properties

### Table 1

Knot Identification of FS Tau B Jet

| Knot | Proper Motion\(^a\) | 1997 | 2007\(^b\) | Knot | 1997 | 2007\(^b\) | Knot | 2007 |

revealed by the spectra and the intensity difference shown in the image indicate that the physical conditions in the two sides of the jet may be different. We combine our new [Fe ii] spectroimaging results with previous optical data in the literature to provide a more complete picture of the asymmetry.

The [Fe ii] spectra provide the first spatially resolved spectra for the FS Tau B jet close to the source at a sub-arcsecond scale. Previous optical spectra obtained by Eislöffel & Mundt (1998), at a resolution of ~1", have shown that the velocity ratio of the blueshifted jet to the redshifted counterjet is ~1.24 and that the jet has a larger line width (100 to 200 km s^{-1}) than the counterjet (~40 km s^{-1}) at the positions close to the source. In our [Fe ii] spectra, the speeds for both the jet and the counterjet are larger than those found in the [S ii] spectra by ≥20%, resulting in a more pronounced velocity ratio of 1.34 ± 0.05. The different velocity ratios derived from lines of different species may result from different critical densities that trace different portions of the jet. The [Fe ii] line has critical density ~10 times that of [S ii] (2 × 10^{4} cm^{-3} compared to 2 × 10^{5} cm^{-3}) and may be able to trace the denser and faster inner part of the jet. Such a difference was also found in the asymmetric RW Aur A jet (e.g., Woitas et al. 2002b; Pyo et al. 2006).

The spectrally resolved [Fe ii] knot permits a qualitative comparison with wind models. In the X-wind model, the wind is driven from the inner edge of the disk, from which the streamlines diverge almost radially with the same flow speed. With a projected jet velocity centroid V_{j} and inclination i, the most blueshifted velocity will occur at the deprojected speed V_{j} / \cos i. This sets the scale of the line width. The innermost blueshifted knot of the FS Tau B jet has a velocity centroid at ~75 km s^{-1} with an FWHM of ~110 km s^{-1}. With i = 70°, the deprojected speed is ~220 km s^{-1} for the blueshifted jet. The FWHM of ~110 km s^{-1} is consistent with that predicted by the X-wind model. Such a large line width close to the driving source was also observed in the blueshifted jet from RW Aur A, with a value ~100 km s^{-1} (Pyo et al. 2006). The counterjet would be expected to have a similar scale of line widths close to the driving source. However, the imperfect subtraction of telluric lines and possible disk occultation (discussed below) would complicate the determination of the line widths at the redshifted side.

Flux asymmetry between the jet and counterjet was observed in our [Fe ii] image as well as in the optical images obtained with HST/WFPC2 (Krist et al. 1998; Woitas et al. 2002a). For [Fe ii] and WFPC2 R-band images, the peak brightness ratio between the jet knot A and counterjet knot D' is below 0.3, while that in the Hα and [S ii] images is ~2. The apparent discrepancy was attributed to different treatments of pixel scales when mosaicking WFPC2 CCDs. With reanalysis with the standard MultiDrizzle procedure, the ratio becomes ~0.5 for the narrowband images. It is puzzling that the [Fe ii] flux ratio between the jet and counterjet changes from 1/7 to ~3 within 2" from the source. One possibility is the differential extinction between the two sides of the jet. However, extinction values found in the literature (obtained from optical to infrared imaging and spectroscopic observations) are widely scattered, and the observations do not spatially resolve the knots (e.g., Krist et al. 1998; Padgett et al. 1999; Connelley & Greene 2010). Apparent dimming due to partial disk occultation may explain the flux ratio if one assumes that the two innermost knots were ejected at the same epoch with the 1.34 velocity ratio. An opaque disk with radius 309 ± 18 AU at an inclination of ~70° (Yokogawa et al. 2001) is consistent with this scenario.

The brightness and flux asymmetries observed in both optical and near-infrared wavelengths may result from asymmetries in excitation conditions at the two sides of the disk. Optical spectra taken by Eislöffel & Mundt (1998) showed that the density-sensitive [S ii] λλ6717/6731 ratio is lower in the redshifted counterjet, indicating that the redshifted counterjet has an overall higher electron density. Woitas et al. (2002a) noted that a flux asymmetry occurs in the Hα and [S ii] images, and that the Hα/[S ii] ratio is lower in the redshifted counterjet, suggestive of a lower ionization state. The brighter [Fe ii] counterjet also has an overall higher density than the blueshifted jet. Line intensities combined with the line ratios obtained in both the optical and near-infrared wavelengths suggest that FS Tau B is driving a jet that has different density profiles and excitation conditions on opposite sides.

Properties of the FS Tau B system can be explained by an asymmetry in the mass loss driven from the source. The asymmetry in mass-loss rates could cause an asymmetry in velocity in order to balance the linear momentum ejected. That is, a smaller mass loss would be compensated by a higher jet velocity, and vice versa, because no apparent recoil motion has been reported for such sources. The faster blueshifted jet would have a smaller mass-loss rate which gives rise to fainter [Fe ii] emission and a larger [S ii] doublet ratio. The faster jet would also carry more kinetic energy that could inject more mechanical heating into the jet leading to a larger value of Hα/[S ii] ratio. On the other hand, material on the cavity wall should experience different amounts of shock heating as shown in the brightnesses of Hα along the cavity (Figure 9 of Eislöffel & Mundt 1998).

Ambient material around FS Tau B is likely to be symmetrically distributed as the bipolar cavities are symmetric in morphology (e.g., Eislöffel & Mundt 1998). The asymmetry in the jet alone could deposit different amounts of energy onto the walls through the unseen wide-angle wind that the wide velocity profile near the base manifests. The asymmetric optical emission along the cavities may be the evidence of such interaction.

There are other jet-outflow systems that have an asymmetric jet driving an outflow. The Class I source L1551 IRS 5 has a large-scale Hα nebula surrounding its blueshifted jet (Davis et al. 1995). The redshifted counterjet was not well known due to its high extinction until recent deep [Fe ii] imaging (Hayashi & Pyo 2009). The asymmetry is even more pronounced in that the blueshifted lobe of the molecular outflow carries twice the kinetic energy of the redshifted lobe (Stojimirović et al. 2006). HL Tau, a Class II source, drives a bipolar [S ii] jet with a discernible asymmetry. Velocity of the blueshifted jet is ~200 km s^{-1} while the redshifted counterjet is ~+100 km s^{-1} in the stellar rest frame (Mundt et al. 1990). A similar asymmetry was also noted in the [Fe ii] jet (although with a smaller velocity ratio for yet unknown reasons; Pyo et al. 2006). Transient objects such as FS Tau B and HL Tau are excellent targets to examine the asymmetry in both the jet and its associated wind-ambient interaction.

5 SUMMARY

We have undertaken Subaru/IRCS observations of the FS Tau B system in the H and K bands with [Fe ii] 1.644 μm and H2 2.122 μm lines. We have for the first time detected the jet and counterjet in [Fe ii] image, and spatially resolved the kinematics of the jet and counterjet within 2" of the driving source. The [Fe ii] jet and counterjet clearly exhibit asymmetric properties. At distances >5" from the driving source, the total flux of the counterjet is seven times that of the jet, while within 2" the
blueshifted jet is brighter by a factor of three. The innermost blueshifted knot is 34% faster and shows a larger velocity width than the innermost redshifted knot.

We compare our [Fe II] image and spectra with optical results from archival HST/WFPC2 images and long-slit spectra in the literature. The [Fe II] image shows a stronger brightness asymmetry than do the optical narrowband and broadband images. The asymmetry cannot be due solely to differential extinction. The fainter and faster [Fe II] jet shows the larger [S II] doublet ratio and Hα/[S II] ratio, indicating that it has lower density and higher excitation. This suggests that the FS Tau B jet and counterjet are asymmetric. Interpretation of the observed asymmetries of the innermost knots is complicated by possible differential extinction and disk obscuration.

The FS Tau B system may be explained by an asymmetric bipolar outflow driven with different mass-loss rates. The side with a lower mass-loss rate will drive a jet with a higher speed to maintain momentum balance. Thus, the faster and less dense jet can produce fainter [Fe II] emission but a larger Hα/[S II] ratio since it carries more kinetic energy. The difference in brightness of Hα knots seen on two sides of the cavity can also be explained as different amounts of energy impinging onto the wall, giving rise to higher ionization on the faster side. This naturally produces the observational results without any assumptions about the properties of the ambient medium. This confluence of detailed observations and models makes FS Tau B a promising laboratory for testing models of the origins of protostellar outflows.

The authors thank the anonymous referee whose comments significantly improved the presentation and clarity of the manuscript. HST/WFPC2 images used for comparisons were obtained from the Multimission Archive at the Space Telescope Science Institute (MAST). STScI is operated by the Association of Universities for Research in Astronomy, Inc., under the NASA contract NAS5-26555.
