Objectives: The significance of early ischemic changes (EIC) on computed tomography (CT) within 3 hours after stroke onset remains controversial. The semi-quantitative Alberta Stroke Program Early CT Score (ASPECTS) is found to have prognostic value in early stroke. This study assesses factors associated with the presence of EIC and the relation between EIC and clinical outcome.

Materials and methods: CT scans from 61 consecutive patients receiving thrombolytic therapy were reviewed by 3 experienced stroke neurologists, assessing EIC (ASPECTS) and vascular signs (hyperdense middle cerebral artery stem and/or branches). Short-term outcome was assessed with the National Institute of Health Stroke Scale at 24 hours and long-term outcome with the modified Rankin Scale score after 3 months.

Results: The prevalence of EIC was 54% and the agreement between assessors was good (kappa 0.52–0.67). EIC was independently associated with younger age and absence of diabetes mellitus. Neither EIC nor vascular signs were associated with 3-months outcome.

Conclusions: ASPECTS is as simple, systematic approach to assessing EIC, and the inter-observer agreement is good. Patient age and diabetes mellitus influence the presence of EIC.

Keywords: acute stroke, computed tomography, ischemia, thrombolysis

Introduction
Intravenous recombinant tissue plasminogen activator (tPA) improves outcome after acute ischemic stroke (NINDS 1995; Hacke et al 2004). Outcome is influenced by a number of factors like age, treatment delay, diabetes mellitus, hypertension, and possibly also early ischemic changes (EIC) on baseline computed tomography (CT). EIC may represent cytotoxic edema and irreversible injury (del Zoppo et al 1998) and are associated with unfavorable outcome (Barber et al 2000). It has been suggested that early major ischemic changes on CT should preclude use of tPA (von Kummer 2003), but controversies on this topic remain (Lyden 2003; Demchuk et al 2005). Appropriate patient selection for thrombolysis is important and needs to be refined. The Alberta Stroke Program Early CT Score (ASPECTS) is a reproducible grading system and a potentially valuable tool for studying early ischemic changes (Barber et al 2000; Coutts et al 2004a). The aim of this study was to assess factors associated with the presence of early ischemic changes and their relation to good clinical outcome, and to assess inter-observer agreement among experienced stroke neurologists using the ASPECTS system.

Materials and methods
From May 1998 to October 2003, 67 patients with acute ischemic stroke affecting the middle cerebral artery (MCA) territory received thrombolytic treatment with 0.9 mg/kg recombinant tissue plasminogen activator (tPA) (alteplase; Actilyse®, Boehringer Ingelheim) in accordance with the National Institute of Neurological Disorders and Stroke (NINDS) tPA Stroke Study protocol (NINDS 1995) and the European Stroke
Statistics. Short-term outcome (24 h after stroke onset) was analyzed based on linear regression, with NIHSS score after 24 h as the dependent variable. Chi-square test, Mann-Whitney test and Fisher’s exact test were performed when appropriate. Variables possibly associated with the consensus ASPECT score were evaluated by linear regression analysis using the consensus ASPECT score as the dependent variable. The analysis was performed with Statistical Package for the Social Science 11.0.1 for Windows (SPSS Inc., Chicago, IL, USA).

**Results**

Six (9%) out of 67 patients were excluded from the study due to poor quality CT scans which did not allow an exact assessment. The ASPECT score was obtained in the remaining 61 patients based on CT scans performed within three hours (mean 104 minutes) of stroke onset. Patient demographics are shown in Table 1 for patients with ASPECT score ≤7 versus >7.

Table 2 shows the results of the linear regression analysis with the ASPECT score as the dependent variable. The linear regression analysis showed that higher ASPECT score was independently associated with old age (P = 0.004), low NIHSS score on admission (P = 0.006), presence of diabetes mellitus (P = 0.018), and short time from stroke onset to CT (P = 0.044).

Unfavorable short-term outcome (based on the NIHSS score 24 hours after stroke onset) was independently associated with low ASPECTS score (partial correlation = −0.367, P = 0.005) and diabetes mellitus (partial correlation = 0.267, P = 0.043). Long-term unfavorable functional outcome (mRS ≥ 3) at 3 months was associated with high NIHSS score on admittance (P < 0.001, Mann-Whitney test).

**Table 1 Demographics of ischemic stroke patients with ASPECTS scores ≤7 and >7 based on initial CT before receiving thrombolysis**

|                         | ASPECTS ≤7 | ASPECTS >7 | P     |
|-------------------------|------------|------------|-------|
| Male, %                 | 79         | 57         | 0.214 |
| Age, years (mean)       | 59         | 68         | 0.019 |
| Left hemisphere, %      | 57         | 77         | 0.184 |
| Diabetes mellitus, %    | 0          | 17         | 0.180 |
| Hypertension, %         | 36         | 38         | 1.000 |
| Smoking, %              | 33         | 25         | 0.715 |
| Onset to CT, minutes (mean) | 104     | 104        | 0.971 |
| NIHSS on admission (median) | 16       | 13         | 0.174 |
| NIHSS 24 hours (median) | 13         | 8          | 0.064 |

**Abbreviations:** ASPECTS, Alberta Stroke Program Early CT Score; CT, Computed Tomography; NIHSS, National Institute of Health Stroke Scale.
CT and thrombolysis in acute stroke

Any early ischemic sign (ie, ASPECTS <10 vs. 10) was not associated with unfavorable functional outcome at 3 months ($P = 0.56$, Fisher’s exact test), neither was HMCA sign ($P = 0.37$) nor MCAD sign ($P = 1.00$).

Six (9%) patients suffered cerebral hemorrhagic complications, of which two (3%) were symptomatic. There was no association between ASPECTS and hemorrhage.

The kappa ($\kappa$) statistics between 3 neurologists as to ASPECT score ranged pair-wise from 0.52 to 0.67 ($P < 0.001$). Based on the consensus score, the prevalence of early ischemic changes was 54%. Fourteen (23%) patients had ASPECT score $\leq 7$ and 47 (77%) patients ASPECTS score $>7$. Figure 1 shows the distribution of the ASPECT score.

The prevalence of vascular pathology signs was 43%, 18% had a hyperdense proximal MCA (HMCA) sign, 18% a hyperdense distal MCA “dot” (MCAD) sign, and 7% had both. The $\kappa$-statistics between 3 neurologists as to HMCA sign ranged pair-wise from 0.44 to 0.70 ($P = 0.001$). The corresponding $\kappa$-statistics as to MCAD sign ranged from 0.35 to 0.61 ($P = 0.005$).

Discussion

Early ischemic changes (EIC) on CT within 3 hours were independently associated with younger age and absence of diabetes mellitus in this study (Table 2). It is conceivable that cerebral pathology such as leukoaraiosis and atrophy associated with diabetes and old age makes it difficult to detect minor EIC, leaving younger patients with an apparently higher prevalence of ischemic changes. It is possible that younger patients show a better grey – white distinction in normal brain tissue making EIC easier to detect. The higher prevalence of EIC among younger patients may cause underutilization of thrombolysis in this age group. Supporting our findings, a relationship between younger age and CT changes has been found also in a small study assessing CT scans within 12 hours after stroke onset (Jaillard et al 2002). By contrast, in the NINDS rtPA Stroke Study, age was not correlated with ASPECTS (Demchuk et al 2005).

Based on the ECASS trials many centers exclude patients with early ischemic changes exceeding 1/3 third of the MCA area (von Kummer 2003), even though this was not shown to impact outcome in the NINDS trial or the Australian Streptokinase Trial (Gilligan et al 2002). Although we did not assess this question, our findings suggest that the >1/3 exclusion criteria might lead to a relatively more frequent exclusion of younger than older ischemic stroke patients. This selection bias may have contributed to the reported better outcome of younger ischemic stroke patients treated with tPA compared with older patients.

We found that short time from stroke onset to CT, and low NIHSS score on admittance were independently associated with high ASPECTS in a three hour time window (Table 2). These results were as expected.

The prevalence of EIC in this study was 54%. This is comparable with other studies reporting a prevalence of EIC between 41% and 77% within the 3-hour time window (Grotta et al 1999; Barber et al 2000; Barber et al 2001; Demchuk et al 2005). One reason for the varying prevalence could be technical, as newer generation CT scanners with improved tissue contrast and spatial resolution may show more EIC than older ones. Another reason may be differences in time delay until baseline CT, as EIC become increasingly visible over time even within the 3-hour time window (Patel et al 2001). A possible reason may also be that there is a general lack of definitions for EIC (Wardlaw and Mielke 2005).

Table 2 Linear regression analysis with the ASPECTS score as the dependent variable

|                  | Partial correlation | $P$   |
|------------------|---------------------|-------|
| Gender           | −0.084              | 0.582 |
| Age              | 0.422               | 0.004 |
| NIHSS at admission | −0.401            | 0.006 |
| Time to CT       | −0.301              | 0.044 |
| Diabetes mellitus| 0.352               | 0.018 |
| Hypertension     | −0.015              | 0.924 |
| Smoking          | 0.001               | 0.993 |

Although high ASPECT score was independently associated with favorable short-term prognosis at 24 h, we did not find any association between EIC and long-term outcome at three months. One possible explanation for this discrepancy may be that some EIC are reversible (Jaillard et al 2002). Subtle changes like focal swelling may reflect mild reversible tissue edema (Lyden 2003; Butcher et al 2007) or vasodilatation (Jaillard et al 2002) and may thus correlate more to short-term neurological dysfunction than to neuronal injury and long-term prognosis. More obvious hypodensity may reflect irreversibly damaged ischemic brain tissue and may thereby have long-term prognostic value. We also found no association between vascular signs (HMCAS, MCADS) and outcome at 3 months. This is in accordance with earlier data (Barber et al 2001). The lack of association between ASPECTS and prognosis in this study is in accordance with earlier studies on EIC (Patel et al 2001; Gilligan et al 2002; Dzialowski et al 2006) but in contrast to other studies of ASPECTS and tPA treatment within the 3 hour time window (Barber et al 2000; Coutts et al 2004b; Demchuk et al 2005). Exclusion of patients for thrombolysis based on ASPECT score or vascular signs within the first three hours after stroke onset, is therefore not supported by our study. Caution in the use of ASPECTS at predicting the outcome of individual patients is warranted (Weir et al 2006). Clear definitions of EIC with differentiation between subtle changes and obvious hypodensity and a well-defined time axis may improve the prognostic accuracy of the ASPECT score in future studies.

In this study the κ statistics for agreement between 3 neurologists was good (0.52–0.67). This is compatible with κ values for inter-observer agreement in other studies (κ 0.20–0.88) assessing early CT changes within 3 hours after stroke onset (Grotta et al 1999; Barber et al 2001; Fiebach et al 2002). In a systematic review of 15 studies of observer reliability (Wardlaw and Mielke 2005) the range of κ values was 0.14–0.78 for any early sign of infarction within 6 hours after stroke onset. The highest levels of agreement were those for the HMCAS, for which the κ values ranged from 0.36 to 1.00. This was also found in our study (κ 0.44–0.70). The ECASS trial investigators (von Kummer 1998) and others (Wardlaw and Mielke 2005) have shown that training results in a significant improvement in the detection of early ischemic changes. The good inter-observer agreement among trained assessors in this study supports the value of systematic training. The assessors had knowledge of the affected side, which might influence the results. However, in previous studies this knowledge did not change inter-observer agreement significantly (Tomsick et al 1990; von Kummer et al 1996; Wardlaw et al 1999).

In conclusion, this study shows that the ASPECTS is a systematic, robust, and practical method for evaluating early ischemic changes on CT scans when performed by experienced neurologists. High ASPECT score was associated with favorable very short-term outcome, but this association disappeared on 3 months follow-up in patients treated with intravenous tPA. A relationship between younger age and CT changes exists and a lower ASPECT score among younger patients may cause underutilization of thrombolysis in this age group.
