ABSTRACT

It is shown that the commonly held view of sharp Fe K edges must be modified if the decay pathways of the resonances converging to the K thresholds are adequately taken into account. These resonances display damped Lorentzian profiles of nearly constant widths along the spectroscopic series that are smeared to impose continuity across the threshold. By modeling the effects of K damping on opacities, it is found that the broadening of the K edge grows with the ionization level of the plasma and that the appearance at high ionization of a localized absorption feature around 7.2 keV is identified as the Kβ unresolved transition array.

Subject headings: atomic processes — line: formation — line: profiles — X-rays: general

1. INTRODUCTION

Absorption and emission features arising from iron K-shell processes are observed in the majority of X-ray spectra and are therefore of practical importance in high-energy astrophysics. This is primarily due to the iron cosmic abundance but also to the relatively unconfused spectral region where they appear. Although the observational technology in X-ray astronomy is still evolving, many of these features are being resolved and exploited as plasma diagnostics. In this respect, they are naturally grouped according to their origin, i.e., bound-bound or bound-free ionic transitions, and much of the interpretation of the latter has relied on atomic calculations (Verner & Yakovlev 1995; Berrington, Quigley, & Zhang 1997; Donnelly et al. 2000; Berrington & Ballance 2001) that predict a sharp increase of the photoabsorption cross section at the K-shell threshold. The purpose of this communication is to emphasize that this commonly held view is incorrect because of an oversimplified treatment of the decay pathways of the resonances converging to this limit and that previous astrophysical inferences from K-edge structures should thus be revised.

2. CONSTANCY OF K DAMPING

When a photon is sufficiently energetic to promote a K-shell electron to an excited Rydberg state, the latter decays through both radiative and autoionization (Auger) transitions. Illustrating these processes in the relatively simple case of Ne-like Fe XVII, the photoexcited K-vacancy states that

\[ h\nu + 1s^22s^22p^6 \rightarrow 1s^22s^22p^6np \]

and

\[ \begin{align*}
1s^22s^22p^5np + e^- \\
\rightarrow 1s^22s2p^6 np + e^- \\
\rightarrow 1s^22p^6np + e^-.
\end{align*} \]

The radiative branches are controlled, as indicated in equations (2) and (3), by the Kα (2p → 1s) array at ~λ1.93 Å and the Kn (np → 1s), of which the most salient is the Kβ array at ~λ1.72 Å. C. Mendoza, P. Palmeri, T. Kallman, & M. Bautista (2002, in preparation, hereafter MPKB) have recently demonstrated that for any K-vacancy fine-structure state in the Fe isonuclear sequence, the width ratio \( \Gamma(\beta) : \Gamma(\alpha) \leq 0.23 \).

Equation (4) contains the participator Auger (KLn) channels in which the np outer electron is directly involved in the decay. By contrast, in the KLL channels (eq. [5]), the np Rydberg electron remains a spectator. It has also been demonstrated by MPKB that for any Fe K-vacancy fine-structure state with a filled L shell, the total Kα and KLL widths are practically independent of both the principal quantum number \( n \geq 3 \) of the outer-electron configuration and the electron occupancy \( N > 9 \), and they keep a ratio of \( \Gamma(KLL) : \Gamma(\alpha) \sim 1.5 \). These findings illustrate the application of Gauss’s law at the atomic scale as previously discussed by Manson, Theodosiou, & Inokuti (1991) in the context of the inner-shell properties of Kr and Sn. Small quantum-mechanical deviations may occur via shake processes caused by a strong admixture of levels with different outer-electron configurations; for Fe ions with \( 10 \leq N \leq 17 \), for instance, the variations in the Kα widths by such processes have been estimated to be less than 5%. Furthermore, MPKB have also determined that Auger decay is 94% dominated by the KLL channels in Fe XVII and by no less than 76% in Fe X. Furthermore, preliminary calculations for other members of the Fe isonuclear sequence with \( N > 17 \) indicate that the KLL branching ratio is not significantly reduced even though the stronger of the KLM and KMM branches become spectator processes. Since both the participator Kr and KLN widths decrease with the effective quantum number as \( \sim(n^*)^{-3} \), the total widths of K-vacancy states within an ionic species may be assumed constant for \( n \rightarrow \infty \); for members with a filled L shell, they are also to a good approximation independent of \( N \). In line with the previous discussions by Gorczyca (2000) and Gorczyca & McLaughlin (2000), the width constancy of high-\( n \) K resonances imprints distinctive signatures on the threshold structures of the photoabsorption cross sections that have actually been measured in the laboratory in

O I and Ne I but that have been seriously underestimated in many atomic calculations.

3. THE Fe xvii CASE

Traditional scattering approaches may present difficulties in treating the effects of spectator Auger decay. For instance, the Breit-Pauli R-matrix (BPRM) method (Berrington et al. 1978) is based on the close-coupling approximation whereby the wave functions for states of an N-electron target plus a colliding electron are expanded in terms of a finite number of target eigenfunctions. As can be deduced from equation (5), BPRM calculations can handle spectator Auger channels only for low-n K resonances since the close-coupling expansion must explicitly include nl target states. However, Gorczyca & Robicheaux (1999) have modified the BPRM to implicitly account for the spectator Auger channels by means of an optical potential devised from multichannel quantum defect theory. A target-state energy now acquires the imaginary component

$$E_n \rightarrow E_n - i \Gamma_n / 2,$$

where $\Gamma_n$ is its partial decay width. This treatment of spectator Auger decay is thus analogous to that of radiation damping (Robicheaux et al. 1995).

In order to discern the contributions of the KLL channels to the total Auger widths, several BPRM calculations are carried out for the Fe $^{57+} + e^-$ system. First, only target levels from the $1s^2 2s^2 2p^4$, $1s^2 2s^2 2p^5$, and $1s^2 2s^2 2p^6$ configurations are included in the expansion, thus only accounting for participant Auger decay. In a second calculation, levels from the $1s^2 2s^2 2p^7 np$, $1s^2 2s^2 2p^8 np$, and $1s^2 2p^5 np$ configurations with $n \leq 4$ are added to the target representation that now maps out the complete Auger manifold for the $1s^{-1}3p$ and $1s^{-1}4p$ resonances. In Table 1, the resulting Auger widths for these resonances are compared; increases by KLL decay greater than an order of magnitude and constant total Auger widths can be seen.

In a further calculation, the BPRM + optical potential approach of Gorczyca & Robicheaux (1999) is employed to study the effects of radiation and Auger damping on the resonance structure. Figure 1 shows the photoabsorption cross section of the $1s^2 2s^2 2p^6 2S_{1/2}$ ground state of Fe xvii in the near K-threshold region. It may be seen that the undamped cross section is populated by a double series ($1s^{-1}np^{-1}P^j$) of narrow and asymmetric resonances that converge to a sharp K edge. The inclusion of radiation (Ka) and Auger (KLL) damps lead to resonance series with constant widths and symmetric profiles that get progressively smeared with increasing n to produce a smooth transition through the K threshold; in low resolution, the edge would then appear to be downshifted in energy. The symmetric Auger profiles are, as discussed by Nayandin et al. (2001), a consequence of the fact that KLL channels give rise to continuum states that can only be reached by dipole forbidden direct photoionization of the ground state and thus cause the Fano q-parameter to tend toward infinity. With respect to radiation damping, the dominance of the Keα over the Auger participator channels causes the modified Fano q-parameter (Robicheaux et al. 1995) to be large, so as to also yield a symmetric profile. Resonance smoothing is the result of oscillator strength conservation that must enforce an approximate $(n^*)^{-3}$ reduction of the resonance peak value because of the constant widths.

4. K-EDGE SPECTRAL SIGNATURES

An advantage of the simple behavior of K damping is that its impact on opacities can be estimated by means of an analytic model. The latter has been constructed and validated with the BPRM photoabsorption cross section of Fe xvii: the damped $1s^{-1}3p$ resonances are fitted with Lorentzian profiles and extrapolated with $n^*$ assuming constant widths and intensities decreasing with $(n^*)^{-3}$, with the resonance positions being deduced by the usual Ritz formula. The cross sections of all the other Fe ions in the near-threshold region are then determined in a similar fashion assuming a single $1s \rightarrow np$ Rydberg series of Lorentzian resonances for each species with $n \geq 2$ for $4 \leq N \leq 9$, $n \geq 3$ for $10 \leq N \leq 17$, and $n \geq 4$ for $18 \leq N \leq 26$. Since the resonance widths can be assumed constant in systems with $N > 9$ (MPKB), they are assigned the value of the $3p$ resonances in Fe xvii, namely, $4.5 \times 10^{-2}$ ryd. For $N \leq 9$, this value is scaled by a factor of $N(N - 1)/90$. The resonance intensities of the first few members of each series are obtained from

TABLE 1

| State | $E$ (eV) | $\Gamma(K\alpha)^a$ (eV) | $\Gamma(K\alpha + KLL)^a$ (eV) |
|-------|---------|--------------------------|-----------------------------|
| $1s^{-1}3p\,^1P^0$ | 7.187 | $3.80 \times 10^{-2}$ | $6.50 \times 10^{-2}$ |
| $1s^{-1}3p\,^3P^0$ | 7.192 | $2.17 \times 10^{-2}$ | $6.34 \times 10^{-2}$ |
| $1s^{-1}4p\,^1P^0$ | 7.422 | $1.39 \times 10^{-2}$ | $6.15 \times 10^{-2}$ |
| $1s^{-1}4p\,^3P^0$ | 7.425 | $7.95 \times 10^{-3}$ | $6.08 \times 10^{-1}$ |

$^a$ Includes only participant (K\alpha) Auger channels.

$^b$ Includes both participant (K\alpha) and spectator (KLL) Auger channels.

---

Fig. 1.—Total photoabsorption cross section of Fe xvii computed with the BPRM method (a) without damping, (b) with radiation damping, and (c) with both radiation and spectator Auger damping.
multiplet f-values computed with the atomic structure code HFR (Cowan 1981), and the K-threshold positions and background cross sections are taken from Verner & Yakovlev (1995).

The monochromatic opacities are generated with the XSTAR program (Kallman & Bautista 2001); the self-consistent ionization balance and electron temperature are computed under the assumption that ionization and heating are primarily due to an external source of continuum photons and that all processes are in a steady state. Solar abundances and an $F_{\mathrm{e}} \sim \epsilon^{-1}$ continuum power law are adopted. As shown in Figure 2, results are characterized in terms of the familiar ionization parameter $\xi \equiv L/nR^2$ in the range $0.01 \leq \xi \leq 100$, where $L$ is the luminosity of the incident X-ray radiation, $n$ the gas density, and $R$ the distance from the radiation source. Two distinctive spectral signatures emerge: (1) the concept of a sharp edge only applies for low-ionization plasmas ($\log(\xi) \sim -2$), and its progressive broadening is a function of ionization; (2) for $\log(\xi) \geq 0$, a strong absorption feature appears at the piedmont ($\sim 7.2$ keV) caused by the Kβ unresolved transition array (UTA).

The features produced by the smeared resonances on the K-edge opacities really stand out in a comparison with opacities computed with undamped photoabsorption cross sections. The latter can be approximated by replacing the Lorentzian profiles with the Fano type with constant asymmetry parameters $q = 200$, i.e., the undamped value for the $3p$ resonance in Fe xvii. The undamped widths are obtained with HFR for the first member of each series and scaled down by $(n^*)^{-1}$ for the higher.

5. DISCUSSION

Broad K-edge absorption structures have been widely observed in the X-ray spectra of active galactic nuclei and black hole candidates as reviewed by Ebisawa et al. (1994) and more recently reported by Done & Zycki (1999) and Miller et al. (2002). They have been interpreted in terms of the reflection of X-rays by optically thick accretion disks around central compact objects, partial absorption models, and relativistic broadening. Furthermore, an unidentified local absorption feature at $\sim 7$ keV, just below a smeared K-edge, has been reported by Ebisawa et al. (1994) in the bright X-ray nova GS 1124−68 and by Pounds & Reeves (2002) in the Seyfert 1 galaxy MCG −6-30-15; in this respect, the fitted ionization parameter ($\xi \sim 5.9$) in the latter seems to support our predicted edge signatures. It is expected that the present findings will contribute to a more realistic spectral modeling above 7 keV that has recently been described as critical by Pounds & Reeves (2002). However, quantitative...
modeling implies a systematic revision of the inner-shell photoionization cross sections for the Fe isonuclear sequence that is currently underway.
