The in-degree and out-degree distributions of a growing network model are determined. The in-degree is the number of incoming links to a given node (and vice versa for out-degree). The network is built by (i) creation of new nodes which each immediately attach to a pre-existing node, and (ii) creation of new links between pre-existing nodes. This process naturally generates correlated in- and out-degree distributions. When the node and link creation rates are linear functions of node degree, these distributions exhibit distinct power-law forms. By tuning the parameters in these rates to reasonable values, exponents which agree with those of the web graph are obtained.

The world-wide web (WWW) is a rapidly evolving network which now contains nearly $10^9$ nodes. Much recent effort has been devoted to characterizing the underlying directed graph formed by these nodes and their connecting hyperlinks – the so-called “web” graph. In parallel with these developments, a variety of growing network models have recently been introduced and studied. These model networks are built by sequentially adding both nodes and links in a manner which mimics the evolution of real network systems, with the WWW being the most obvious example.

One fundamental characteristic of any graph is the number of links at a node – the node degree. The growing network models cited above predict that the distribution of node degree has a power law form for growth rules in which the probability that a newly-created node attaches to a pre-existing node increases linearly with the degree of the “target” node. This power law behavior strongly contrasts with the Poisson degree distribution of the classical random graphs, where links are randomly created between any pair of pre-existing nodes in the network.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure1.png}
\caption{A node with in-degree $i = 4$, out-degree $j = 5$, and total degree 9.}
\end{figure}

Since web links are directed, the total degree of a node may naturally be resolved into the in-degree – the number of incoming links to a node, and out-degree – the number of outgoing links from a node (Fig. 1). While the total node degree and its distribution are now reasonably understood, little is known about the joint distribution of in-degrees and out-degrees, as well as their correlation. Empirical measurements of the web indicate that in-degree and out-degree distributions exhibit power-law behaviors with different exponents. In this Letter, we solve for the joint distribution in a simple growing network model. We are able to reproduce the observed in-degree and out-degree distributions of the web as well as find correlations between in- and out-degrees of each node.

Our model represents an extension of growing network models with node and link creation to incorporate link directionality. The network growth occurs by two distinct processes (Fig. 2):

(i) With probability $p$, a new node is introduced and it immediately attaches to one of the earlier target nodes in the network. The attachment probability depends only on the in-degree of the target.

(ii) With probability $q = 1 - p$, a new link is created between already existing nodes. The choices of the originating and target nodes depend on the out-degree of the originating node and the in-degree of the target node.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure2.png}
\caption{Illustration of the growth processes in the growing network model: (i) node creation and immediate attachment, and (ii) link creation. In (i) the new node is shaded, while in both (i) and (ii) the new link is dashed.}
\end{figure}

If only process (i) was allowed, the out-degree of each node would be one by construction. Process (ii) has been shown to drive a transition in the network structure. We shall further show that this general model gives a non-trivial out-degree distribution which is distinct from the in-degree distribution.

We begin our analysis by determining the average node degree; this can be done without specification of the at-
attachment and link creation probabilities. Let $N(t)$ be the total number of nodes in the network, and let $I(t)$ and $J(t)$ be the total in-degree and out-degree, respectively.

According to the two basic growth processes enumerated above, at each time step these degrees evolve according to one of the following two possibilities

$$(N, I, J) \rightarrow \begin{cases} (N + 1, I + 1, J + 1) & \text{probability } p, \\ (N, I + 1, J + 1) & \text{probability } q. \end{cases} \quad (1)$$

That is, with probability $p$ a new node and new directed link are created (Fig. 3) so that the number of nodes and both node degrees increase by one. Conversely, with probability $q$ a new directed link is created and the node degrees each increase by one, while the total number of nodes is unchanged. As a result,

$$N(t) = pt, \quad I(t) = J(t) = t, \quad (2)$$

from which we immediately conclude that the average in- and out-degrees, $D_{in} \equiv I(t)/N(t)$ and $D_{out} \equiv J(t)/N(t)$, are both time independent and equal to $1/p$.

To determine the joint degree distributions, we need to specify: (i) the *attachment rate* $A(i, j)$, defined as the probability that a newly-introduced node links to an existing node with $i$ incoming and $j$ outgoing links, and (ii) the *creation rate* $C(i_1, j_1| i_2, j_2)$, defined as the probability of adding a new link from a $(i_1, j_1)$ node to a $(i_2, j_2)$ node. We restrict the form of these rates to those which we naturally expect to occur in systems such as the web graph. First, we assume that the attachment rate depends only on the in-degree of the target node, $A(i, j) = A_i$. We also assume that the link creation rate depends only on the out-degree of the node from which it emanates and the in-degree of the target node, that is, $C(i_1, j_1| i_2, j_2) = C(j_1, i_2)$.

On general grounds, the attachment and creation rates $A_i$ and $C(j, i)$ should be non-decreasing functions of $i$ and $j$. For example, a web-page designer is more likely to construct hyperlinks to well-known pages rather than to obscure pages. Similarly, a web page with many outgoing hyperlinks is more likely to create even more hyperlinks. We have found that the degree distributions exhibit qualitatively different behaviors depending on whether the asymptotic dependence of the rates $A_i$ and $C(j, i)$ on both $i$ and $j$ grow slower than linearly, linearly, or faster than linearly. The first and last cases lead to either rapidly decaying degree distributions or to the dominance of a single node; this same behavior was already found for the total node degree (4). The most interesting behavior arises for asymptotically linear rates, and we focus on this class of models in our investigations.

Specifically, we consider the model with attachment and creation rates which are shifted linear functions in all indices (*linear-bilinear rates*)

$$A_i = i + \lambda, \quad C(j, i) = (i + \lambda)(j + \mu). \quad (3)$$

An intuitively natural feature of this model is that both the attachment and creation rates have the same dependence on the popularity of the target node. The parameters $\lambda$ and $\mu$ in the rates of Eq. (3) must obey the constraints $\lambda > 0$ and $\mu > -1$ to ensure that the corresponding rates are positive for all permissible values of in- and out-degrees, $i \geq 0$ and $j \geq 1$.

As the network grows, the joint degree distribution, $N_{ij}(t)$, defined as the average number of nodes with $i$ incoming and $j$ outgoing links, builds up. To solve for $N_{ij}(t)$, we shall use the rate equation approach, which has recently been applied to simpler versions of growing networks (1, 2, 3). When the attachment and creation rates are given by Eq. (3), the degree distribution $N_{ij}(t)$ evolves according to the rate equations

$$\frac{dN_{ij}}{dt} = (p + q) \left( \frac{(i - 1 + \lambda)N_{i-1,j} - (i + \lambda)N_{ij}}{I + \lambda N} \right) + \frac{q(j - 1 + \mu)N_{i,j-1} - (j + \mu)N_{ij}}{J + J N} + p \delta_{i0}\delta_{j1}. \quad (4)$$

The first group of terms on the right-hand side account for the changes in the in-degree of target nodes. These changes arise by simultaneous creation of a new node and link (with probability $p$) or by creation of a new link only (with probability $q$). For example, the creation of a link to a node with in-degree $i$ leads to a loss in the number of such nodes. This occurs with rate $(p + q)(i + \lambda)N_{ij}$, divided by the appropriate normalization factor $\sum_{i,j}(i + \lambda)N_{ij} = I + \lambda N$. The factor $p + q = 1$ in Eq. (4) has been written to make explicit the two types of relevant processes. Similarly, the terms in the second group of terms accounts for changes in the out-degree. These occur due to the creation of new links between already existing nodes -- hence the prefactor $q$. The last term accounts for the continuous introduction of new nodes with no incoming links and one outgoing link. As a useful self-consistency check, we can easily verify that the total number of nodes, $N = \sum_{i,j}N_{ij}$, obeys $N = pt$, in agreement with Eq. (3). In the same spirit, the total in- and out-degrees, $I = \sum_{i,j}iN_{ij}$ and $J = \sum_{i,j}jN_{ij}$, obey $I = J = t$.

By solving the first few of Eqs. (3), it is clear that the $N_{ij}$ grow linearly with time. Accordingly, we substitute $N_{ij}(t) = t n_{ij}$, as well as $N = pt$ and $I = J = t$, into Eqs. (3) to yield a recursion relation for $n_{ij}$. Using the shorthand notations,

$$a = q \frac{1 + \lambda}{1 + \mu} \quad \text{and} \quad b = 1 + (1 + p)\lambda,$$

the recursion relation for $n_{ij}$ simplifies to

$$[i + a(j + \mu) + b]n_{ij} = (i - 1 + \lambda)n_{i-1,j} + a(j - 1 + \mu)n_{i,j-1} + p(1 + \lambda)\delta_{i0}\delta_{j1}. \quad (5)$$

We first consider the in-degree and out-degree distributions, $I_i(t) = \sum_j N_{ij}(t)$ and $O_j(t) = \sum_i N_{ij}(t)$. Because
simplifies when \( \nu \) appears to be no simple general expression for the joint distribution: the ratio of two gamma functions. Then we can express \( n_{ij} \) as the sum of two such ratios, \( \nu \) depends on \( \mu \) (an out-degree feature). Notice also that both the exponents are greater than 2.

We can also solve the recursion relation \( \rho \) for \( n_{ij} \) when \( i \) or \( j \) is small. For example, we can express \( n_{i1} \) as the ratio of two gamma functions. Then we can express \( n_{i2} \) as the sum of two such ratios, \( \nu \) appears to be no simple general expression for the joint distribution, we can extract the limiting behaviors of \( n_{ij} \) when \( i \) or \( j \) is large. We find

\[
\begin{align*}
 n_{ij} & \sim \begin{cases} 
 i^{-\xi_{in}}j^\mu, & 1 \ll j \ll i; \\
 j^{-\xi_{out}}i^{\lambda-1}, & 1 \ll i \ll j;
\end{cases} \\
 \xi_{in} & = \nu_{in} + \frac{q}{p} \left( \frac{\nu_{in} - 1}{\nu_{out} - 1} \right) \\
 \xi_{out} & = \nu_{out} + \frac{1}{p} \left( \frac{\nu_{out} - 1}{\nu_{in} - 1} \right).
\end{align*}
\]

Thus the in- and out-degrees of a node are correlated – otherwise, we would have \( n_{ij} = I_iO_j \sim i^{-\nu_{in}}j^{-\nu_{out}} \). This correlation between node degrees is our second basic result.

The analytical form of the joint distribution greatly simplifies when \( \nu_{in} = \nu_{out} \), corresponding to \( a = 1 \) and \( \mu + b = 2\lambda \). In this region of the parameter space, the recursion relation \( \rho \) reduces to

\[
(i + j + 2\lambda)n_{ij} = (i + 1 + \lambda)n_{i-1,j} + (j + 1 + \mu)n_{i,j-1} + p(1 + p\lambda)\delta_{0,j}.
\]

Equation \( \rho \) is simpler than the general recursion \( \rho \) since the node degrees \( i \) and \( j \) now appear with equal prefactors. This feature allows us to transform Eq. \( \rho \) into a constant-coefficient recursion relation. Indeed, the substitution

\[
n_{ij} = \frac{\Gamma(i + \lambda)\Gamma(j + \mu)}{\Gamma(i + j + 2\lambda + 1)} m_{ij}
\]

reduces \( \rho \) to

\[
m_{ij} = m_{i-1,j} + m_{i,j-1} + \gamma \delta_{0,j},
\]

with \( \gamma = p(1 + p\lambda)\Gamma(1 + 2\lambda)/\Gamma(\lambda)\Gamma(\mu + 1) \). We solve Eq. \( \rho \) by the generating function technique. Multiplying Eq. \( \rho \) by \( x^i y^j \) and summing over all \( i \geq 0, j \geq 1 \) yields

\[
\mathcal{M}(x, y) \equiv \sum_{i=0}^{\infty} \sum_{j=1}^{\infty} m_{ij} x^i y^j = \frac{\gamma y}{1 - x - y}.
\]

Expanding this latter expression we obtain

\[
m_{ij} = \gamma \frac{\Gamma(i + j)}{\Gamma(i + j + 2\lambda + 1)}. \tag{18}
\]

Combining Eqs. \( \rho \) and \( \rho \) gives the joint in- and out-degree distribution

\[
n_{ij} = \gamma \frac{\Gamma(i + \lambda)\Gamma(j + \mu)\Gamma(i + j)}{\Gamma(i + j + 2\lambda + 1)}. \tag{19}
\]

In analogy to Eq. \( \rho \), this joint distribution reduces to

\[
n_{ij} = \gamma \frac{j^{\lambda-1}i^\mu}{(i + j)^{2\lambda+1}}. \tag{20}
\]

in the limit \( i \rightarrow \infty \) and \( j \rightarrow \infty \).

Another manifestation of the correlation in the degree distribution becomes evident by fixing the in-degree \( i \) and allowing the out-degree \( j \) to vary. We find that \( n_{ij} \) reaches a maximum value when \( j = i\mu/[2 + (1 + p)\lambda] \) (here we consider large \( i \) and assume that \( \mu > 0 \)). Correspondingly, the average out-degree always scales linearly with the in-degree, \( \langle j \rangle = i(\mu + 1)/[(1 + p)\lambda] \) (here the coefficient is always positive). Thus popular nodes – those with large in-degree – also tend to have large out-degrees. A dual property also holds: Nodes with large out-degree – those where many links originate – also tend to be popular.

Let us now compare our predictions with empirical observations for the world-wide web. The relevant results for the node degrees are \( \rho \)

\[
\nu_{in} \approx 2.1, \quad \nu_{out} \approx 2.7, \quad D_{in} = D_{out} \approx 7.5, \tag{21}
\]
Setting the observed value $D_{in} = D_{out} = 7.5$ to $p^{-1}$ (see the discussion following Eq. (3)) we see that the predictions $\xi_{in} \approx 5.0$ and $\xi_{out} \approx 3.9$. Empirical measurements of these exponents would provide a definitive test of our model.

We have also investigated a simplified model with node creation rate $A_i = i + \lambda$, as above, but with link creation rate $C(j, i) = j + \mu$, which does not depend on the popularity of the target node $i$ (linear-linear rates). For this model, the rate equations for the evolution of the number of nodes with degrees $(i, j)$ have a similar structure to Eqs. (9) and they can be solved by the same approach as that given for the network with linear-bilinear growth rates. We find that the in- and out-degree distributions are dynamically generated. Within this class of models, the linear-bilinear growth rates appears to be a viable candidate for describing the link structure of the web. The model also predicts power-law behavior when $e.g.$, the in-degree is fixed and the out-degree varies. Significant correlations between the in- and out-degrees of a node develop spontaneously, in agreement with everyday experience. Quantitative measurements of correlations in the web graph would test our model and help construct a more realistic model of the world-wide web.
