Two tyrosine residues, Tyr-108 and Tyr-503, are responsible for the deprotonation of phenolic substrates in vanillyl-alcohol oxidase

Received for publication, February 10, 2017, and in revised form, July 5, 2017. Published, Papers in Press, July 17, 2017, DOI 10.1074/jbc.M117.778449

Edited by F. Peter Guengerich

A number of oxidoreductases from the VAO/para-cresol methylhydroxylase flavoprotein family catalyze the oxidation of para-substituted phenols. One of the best-studied is vanillyl-alcohol oxidase (VAO) from the fungus Penicillium simplicissimum. For oxidation of phenols by VAO to occur, it must first be bound in the active site of the enzyme in their phenolate anion form. The crystal structure of VAO reveals that two tyrosine residues, Tyr-108 and Tyr-503, are positioned to facilitate this deprotonation. To investigate their role in catalysis, we created three VAO variants, Y108F, Y503F, and Y108F/Y503F, and studied their biochemical properties. Steady-state kinetics indicated that the presence of at least one of the tyrosine residues is essential for efficient catalysis by VAO. Stopped-flow kinetics revealed that the reduction of VAO by chavicol or vanillyl alcohol occurs at two different rates: \(k_{\text{obs 1}}\), which corresponds to its reaction with the deprotonated form of the substrate, and \(k_{\text{obs 2}}\), which corresponds to its reaction with the protonated form of the substrate. In Y108F, Y503F, and Y108F/Y503F, the relative contribution of \(k_{\text{obs 2}}\) to the reduction is larger than in wild-type VAO, suggesting deprotonation is impaired in these variants. Binding studies disclosed that the competitive inhibitor isoeugenol is predominantly in its deprotonated form when bound to wild-type VAO, but predominantly in its protonated form when bound to the variants. These results indicate that Tyr-108 and Tyr-503 are responsible for the activation of substrates in VAO, providing new insights into the catalytic mechanism of VAO and related enzymes that oxidize para-substituted phenols.

Vanillyl-alcohol oxidase (VAO) (EC 1.1.3.38) from Penicillium simplicissimum is a flavin-dependent oxidase that catalyzes the oxidation of para-substituted phenolic compounds using molecular oxygen as an electron acceptor (1–3). It is a 64-kDa (560 amino acid) protein that forms octameric structures with each subunit containing an FAD cofactor that is covalently linked to the protein via an 8α-N3-histidyl-FAD bond (4). VAO is a member of the VAO/para-cresol methylhydroxylase (PCMH) flavoprotein family, which consists of homologous oxidoreductases that catalyze a wide range of reactions, but share a conserved FAD-binding domain (5). Although VAO catalyzes a range of reactions, such as the oxidation of benzylic alcohols to aldehydes, the oxidative deamination of benzylic amines, the hydroxylation of 4-allylphenols, and the hydroxylation or dehydrogenation of 4-alkylphenols, it displays a strict selectivity toward the oxidation of para-substituted phenols at the C\(\alpha\) atom of their side chain. The proposed catalytic mechanism of VAO provides an explanation for this selectivity (Fig. 1A) (2, 6, 7). First, the substrates of VAO are bound in the active site in their deprotonated phenolate form. Subsequently, a hydride anion is transferred from the C\(\alpha\) atom of the side chain of the substrate to the N5 atom of FAD, yielding the reduced enzyme and a para-quinone methide intermediate. Finally, this intermediate either reacts with water or rearranges to yield the product of the reaction, and FAD is reoxidized by molecular oxygen, which is converted to hydrogen peroxide. The initial deprotonation of the phenolic hydroxyl group of the substrate is likely a crucial step in this mechanism, as it promotes the hydride-transfer reaction by enabling the formation of the para-quinone methide intermediate. Studies using the competitive inhibitor isoeugenol (Fig. 1B) revealed that its \(pK_a\) is lowered from 10 to 5 upon binding to VAO (2). A potential explanation for this decrease is provided by examining the crystal structure of VAO in complex with isoeugenol (4). Three polar residues, Tyr-108, Tyr-503, and Arg-504, form a phenolate-binding pocket, with their side chains positioned within hydrogen bonding distance of phenolic hydroxyl group of the isoeugenol (Fig. 2A). These residues may facilitate deprotonation of the substrate either by promoting preferential binding of the deprotonated form or by one of the tyrosine residues acting as a base and actively deprotonating the substrate in the active site. All three residues are conserved in the homologous flavoenzymes eugenol oxidase (EUGO) and...
para-cresol methylhydroxylase (PCMH, EC 1.17.99.1), which also catalyze the oxidation of para-substituted phenols (8, 9). The role of Arg-474 in PCMH, which corresponds to Arg-504 in VAO, has been studied by site-directed mutagenesis and it was found to be of importance in achieving covalent incorporation of the cofactor of the enzyme and in enabling efficient catalysis by modulating the redox properties of both the cofactor and enzyme-bound substrates (10). Here, we investigated the role played by Tyr-108 and Tyr-503 in VAO using site-directed mutagenesis. Three VAO variants, Y108F, Y503F, and Y108F/Y503F, were created, expressed, and purified and their catalytic properties were studied. Our results reveal that the presence of at least one of these tyrosine residues is essential for efficient catalysis.

Results

The Y108F, Y503F, and Y108F/Y503F variants were successfully expressed in Escherichia coli and purified. Like wild-type (wt)-VAO, all three variants contained a covalently bound FAD cofactor, as judged from the yellow pellet and colorless supernatant obtained after precipitation of the proteins with trichloroacetic acid. In their native form, all variants displayed an octameric quaternary structure, as demonstrated by analytical size exclusion chromatography (data not shown). The flavin absorption spectra of the variants were highly similar to that of wt-VAO (see spectral studies presented below), demonstrating that the introduced mutations do not lead to any major changes in the electronic environment of their flavin cofactor. To determine whether the introduced mutations affect the stability of VAO, thermal midpoints of unfolding of the variants were determined using the ThermoFAD method (11). This yielded thermal midpoints of unfolding of 55 °C for wt-VAO, 53 °C for Y108F and Y503F, and 52 °C for Y108F/Y503F, suggesting the introduced mutations have a minor deleterious effect on the thermostability of VAO.

Steady-state catalytic properties

To determine the effect of the introduced mutations on the catalytic efficiency of VAO, we measured the apparent steady-state catalytic properties of the variants and the wild-type enzyme. The results are presented in Table 1. The catalytic efficiency, measured as kcat/Km, is a measure of the maximum rate of substrate conversion per enzyme molecule under the conditions of the assay divided by the Michaelis constant, which represents the substrate concentration at which the reaction rate is half of the maximum. A higher kcat/Km value indicates a more efficient catalyst.

Figure 1. A, oxidation of vanillyl alcohol as catalyzed by VAO. First, the substrate is bound in the active site in its deprotonated phenolate form. This facilitates the transfer of a hydride anion from the C9 of the substrate to FAD, yielding a para-quinone methide intermediate and the reduced enzyme. This intermediate subsequently rearranges to give the aldehyde product vanillin and FAD is reoxidized by molecular oxygen, which is converted to hydrogen peroxide. B, structures of chavicol and isoeugenol.

Figure 2. Structure of the phenolate-binding pocket of VAO in the wild-type enzyme (A, carbon in white (PDB code 2VAO (4))) and in the Y108F and Y503F variants (B and C, respectively, carbon in gray). The refined 2Fo − Fc electron density map (contoured at 1.2σ) is shown for the mutated residues Y108F and Y503F as blue chicken-wire. The wt-VAO crystal structure in complex with the competitive inhibitor isoeugenol (A, carbon in green) is taken as a reference to analyze the mutant proteins. As reported in Ref. 4, binding of isoeugenol does not significantly influence the geometry of the active site. In B and C, the side chains of Tyr-108 and Tyr-503, respectively, from wt-VAO are shown for comparison. As described in the text, in the Y503F mutant Phe-503 is slightly tilted with respect to the corresponding Tyr-503 in wt-VAO. Tyr-108, Tyr-503, Arg-504, Ser-426, isoeugenol, and the FAD cofactor (carbon in yellow) are displayed in stick representation with the surrounding protein backbone shown in schematic representation. Oxygen atoms are in red, nitrogen atoms in blue, and phosphorous atoms in magenta. Potential hydrogen bonds are depicted as black dashed lines.
state kinetic parameters for the oxidation of two substrates: vanillyl alcohol, which is oxidized to the aldehyde vanillin, and chavicol (Fig. 1B), which is hydroxylated to coumaryl alcohol. The kinetic parameters for the oxidation of these substrates are listed in Table 1. Interestingly, the effect of the mutations varied depending on the substrate. With vanillyl alcohol, the \( k_{\text{cat}} \) drops to \(<2\%\) of that of wt-VAO for both the Y108F and Y503F variants. With chavicol, a more minor drop in the \( k_{\text{cat}} \) value to \(<45\%\) of that of the wild-type enzyme was observed for the Y108F and Y503F variants. With chavicol, the Y108F/Y503F variant displayed a \( k_{\text{cat}} \) value of less than 2\% of that of wt-VAO and with vanillyl alcohol, the activity was too low to accurately determine kinetic parameters. This indicates that the presence of at least one of the two tyrosine residues is essential for effective catalysis. For each variant, the \( K_m \) increased for each substrate. The magnitude of the increase ranged from 3- to 12-fold.

**Stopped-flow kinetics of the reductive half-reaction**

To determine whether the decreased catalytic efficiencies observed for the VAO variants were due to impaired reduction of their FAD cofactor, spectral changes during the anaerobic reduction of the enzymes by vanillyl alcohol or chavicol were followed by stopped-flow spectroscopy. Where possible, photodiode array detection was used to monitor changes over a spectral range from 254 to 725 nm. However, with long measurement times (>10 s), the high-intensity illumination required for this led to photoreduction of FAD. Therefore, in cases where the reduction reaction was slow, it was monitored using single wavelength detection at 439 nm, the absorption maximum of the oxidized FAD in VAO. This was the case for the reduction of the Y108F and Y503F variants by 2 mM vanillyl alcohol and for all reactions involving the Y108F/Y503F variant.

Observed rates for the anaerobic reduction of wt-VAO and the Y108F and Y503F variants by 2 mM vanillyl alcohol at pH 6.2 and 7.5 are given in Table 2. The anaerobic reduction of wt-VAO by vanillyl alcohol at pH 7.5 has been studied previously and was found to be a biphasic process with rate constants at saturating substrate concentrations of \( k_{\text{red1}} = 24 \text{ s}^{-1} \) and \( k_{\text{red2}} = 3.5 \text{ s}^{-1} \). The two different rates of reduction were interpreted to be caused by the presence of two conformations of the enzyme. The rate of the slower phase, \( k_{\text{red2}} \), lies close to \( k_{\text{cat}} \) and is rate-limiting for catalysis. Our results with wt-VAO are in good agreement with these data. The effect of the Y108F and Y503F mutations on the rate of reduction by vanillyl alcohol was similar. In each variant, the reduction was a biphasic process. Each of the rates of reduction has dropped significantly as compared with wt-VAO. The rates of the two phases are in the same range and \( k_{\text{obs}} \) is similar to the rate of steady-state catalysis, suggesting that flavin reduction is rate-limiting in these variants. In addition to the decrease in both reduction rates, the relative contribution of the two kinetic events to the drop in absorption at 439 nm (amplitude \( a \)) has changed. In wt-VAO, \( k_{\text{obs1}} \) has a greater contribution than \( k_{\text{obs2}} \) (\( a_1:a_2 = 2:1 \)), whereas in the Y108F and Y503F variants, \( k_{\text{obs2}} \) has a greater contribution than \( k_{\text{obs1}} \) (\( a_1:a_2 = 1:5 \) for Y108F and 1:3 for Y503F). At pH 6.2, reduction by vanillyl alcohol was also biphasic for all variants. For wt-VAO, the rates of the two phases are very similar to those at pH 7.5. However, their contributions to the reduction have changed, with \( k_{\text{obs2}} \) having a greater contribution than \( k_{\text{obs1}} \) (\( a_1:a_2 = 1:3 \)). In the Y108F and Y503F variants, \( k_{\text{obs1}} \) is somewhat higher than observed at pH 7.5 and \( k_{\text{obs2}} \) is slightly lower in Y108F and does not change significantly in Y503F. As observed for wt-VAO, the contribution of the two rates to the change in absorption shifts, with \( k_{\text{obs2}} \) becoming more predominant (\( a_1:a_2 = 1:32 \) for each variant).

Spectra obtained during the anaerobic reduction of wt-VAO by 100 \( \mu \text{M} \) chavicol are shown in Fig. 3. After mixing wt-VAO with chavicol, the characteristic peak of the oxidized flavin cofactor of the enzyme (maximum at 439 nm) rapidly disappears, indicating that FAD is reduced by the substrate. At the same time, the absorption between 320 and 430 nm increases, yielding an intense peak with a maximum at 373 nm. This peak reaches its maximum intensity after \(~600\) ms, after which it decreases in intensity. The formation of a species with similar spectral characteristics has been observed during the anaerobic reduction of wt-VAO by vanillyl alcohol (\( \lambda_{\text{max}} = 362 \text{ nm} \)) or 4-(methoxymethyl)phenol (\( \lambda_{\text{max}} = 364 \text{ nm} \)) and was attributed to a complex between the quinone methide intermediate and the reduced enzyme formed after the electron-transfer reaction.
has taken place (6). Intermediate spectra obtained upon spectral deconvolution of the stopped-flow data are shown in Fig. 3. The data were fit to a three-phase consecutive model, yielding four distinct spectral intermediates. Species 1 represents the oxidized enzyme. Species 3 displays the highest absorption at 373 nm and complete loss of the characteristic oxidized flavin spectrum. It likely represents the quinone methide-reduced enzyme complex as indicated by its lower absorption at 373 nm, similar to the steady-state reaction rate, suggesting it is rate-limiting for catalysis. The observed rate of decay of the quinone methide intermediate, $k_{\text{obs}3}$, was similar for all variants (0.1–0.2 s$^{-1}$) and is too slow to be catalytically relevant. Presumably, breakdown of this intermediate is faster in the presence of oxygen, as has been observed previously for the quinone methide intermediate formed upon reduction of wt-VAO by 4-(m ethoxy)methyl)phenol (6).

Upon reduction of the Y108F and Y503F variants by chavicol, the spectral changes observed were similar to those seen with wt-VAO, with reduction of FAD occurring concomitantly with the appearance of a putative quinone methide intermediate (Fig. 3). The absorption maximum of this intermediate is shifted to lower wavelengths in the variants (363 nm for Y108F and 368 nm for Y503F) compared with wt-VAO (373 nm).
Table 3

| VAO variant | $k_{obs1}$ | $k_{obs2}$ | $k_{ss}$ |
|-------------|------------|------------|---------|
| pH 7.5      |            |            |         |
| Wild Type   | $139 \pm 1$ (0.76) | $4.5 \pm 0.1$ (0.24) | 6.8 |
| Y108F      | $33 \pm 1$ (0.13) | $1.6 \pm 0.1$ (0.87) | 2.0 |
| Y503F      | $14 \pm 1$ (0.07) | $2.6 \pm 0.1$ (0.93) | 2.3 |
| Y108F/Y503F | $19 \pm 1$ (0.05) | $0.11 \pm 0.01$ (0.95) | 0.069 |
| pH 6.2      |            |            |         |
| Wild Type   | $132 \pm 1$ (0.30) | $3.7 \pm 0.1$ (0.70) |         |
| Y108F      | NO*        | $0.79 \pm 0.01$ (1.00) |         |
| Y503F      | NO         | $1.7 \pm 1$ (1.00) |         |
| Y108F/Y503F | $21 \pm 1$ (0.06) | $0.027 \pm 0.001$ (0.94) |         |

* NO, not observed.

Maximum abundance of the intermediate was observed after 2.2 s for the Y108F variant and after 1.5 s for the Y503F variant, after which the intermediate decays. Spectral deconvolution again revealed a three-phase process (Fig. 3). As with wt-VAO, species 1 and 3 represent the oxidized enzyme and the quinone methide-reduced enzyme complex, respectively. Species 2 again displays an absorption spectrum that is a composite of that of species 1 and 3 and is likely not a real reaction intermediate. Species 4 appears to represent a mixture of quinone methide-reduced enzyme complex and free reduced enzyme. This is likely due to the decay of the quinone methide not being complete at the end of the measurement (120 s). Fitting the data at 440 nm to triple exponential functions revealed that $k_{obs1}$ and $k_{obs2}$ are both decreased in each variant (Table 3). However, neither rate in either variant decreased more than 10-fold. Thus, the effect of the Y108F and Y503F mutations on the rate of reduction of VAO by chavicol is less severe than that on the reduction by vanillyl alcohol ($k_{obs1}$ and $k_{obs2}$ decreased >100-fold in each variant). Interestingly, a similar effect on the relative contributions of $k_{obs1}$ and $k_{obs2}$ to reduction was observed with chavicol as with vanillyl alcohol, with $k_{obs1}$ contributing most in wt-VAO, but $k_{obs2}$ contributing most in the Y108F and Y503F variants. Reduction of the Y108F/Y503F variant by chavicol was monitored using single wavelength detection at 439 nm. In this case, the data fit best to a double exponential function. Interestingly, $k_{obs1}$ is in the same range as for the Y108F and Y503F variants, whereas $k_{obs2}$ is an order of magnitude smaller. This brings it into the same range as $k_{obs3}$ observed for wt-VAO and the Y108F and Y503F variants. This provides an explanation for the absence of a third phase, as the decay of the quinone methide intermediate is now likely no longer distinguishable from the second flavin reduction phase. As with Y108F and Y503F, $k_{obs2}$ makes the largest contribution to flavin reduction. For all variants, $k_{obs2}$ lies close to the observed rate of steady-state catalysis, suggesting it is rate-limiting.

Upon reduction of wt-VAO and the Y108F and Y503F variants by 100 μM chavicol at pH 6.2, similar spectral changes were observed as at pH 7.5. Formation of a quinone methide intermediate and concomitant reduction of FAD were followed by the decay of the quinone methide intermediate, which was too slow to be catalytically relevant. The observed reduction rates are given in Table 3. For wt-VAO, the reduction is a biphasic process. The two rates are similar to those observed at pH 7.5, however, as with vanillyl alcohol, the contribution of the rates to the drop in absorbance changes, with $k_{obs2}$ becoming more predominant ($a_1:a_2 \approx 1:2$ at pH 6.2 compared with $a_1:a_2 \approx 3:1$ at pH 7.5). For the Y108F and Y503F variants, only a single reductive phase was observed, with rate constants that are similar to those of $k_{obs2}$ at pH 7.5, suggesting that the observed rate can be attributed to the same process as $k_{obs2}$ and that the process associated with $k_{obs1}$ does not make an observable contribution to the reduction at pH 6.2. For the Y108F/Y503F variant, the reduction was observed to be biphasic with the rates of the two phases and their relative contributions being similar to those observed at pH 7.5. However, the contribution of the slower phase to the reduction may be underestimated. After reduction of Y108F/Y503F a residual absorbance of 0.03 was measured (usually ~0.015). With the Y108F and Y503F variants it was observed that after the reduction was complete the absorption at 440 nm increased, likely due to the formation of a charge-transfer interaction between the reduced enzyme and a bound substrate molecule. Due to the slow rate of reduction of the Y108F/Y503F variant, formation of such a charge-transfer complex could occur on a similar time scale as the reduction, which would cause part of the absorbance drop associated with the reduction to be masked.

To study the pH dependence of the reaction in more detail, the anaerobic reduction of wt-VAO by 50 μM chavicol was studied in the pH range 6.1–9.5. The overall spectral changes, as monitored using photodiode array detection, were similar to those observed during the experiments presented in Fig. 3 at all pH values. Reduction of FAD and concomitant formation of a quinone methide-reduced enzyme complex was followed by the decay of the quinone methide intermediate to yield the fully reduced enzyme spectrum. As before, the absorption at 440 nm was fit to a triphasic exponential function, yielding two rates that are associated with flavin reduction: $k_{obs1}$ and $k_{obs2}$. The values of $k_{obs1}$ and $k_{obs2}$ remained similar in this pH range, with the lowest and highest values never differing more than a factor 2 (Fig. 4, inset). The pH dependence of the fractional contribution of $k_{obs1}$ to the reduction is shown in Fig. 4. The contribution of $k_{obs1}$ increases with pH. Attempts to fit the data to the Henderson-Hasselbalch equation, which allows the determination of the pKa of an ionizable group were unsuccessful. Although the data display a sigmoidal form, the slope of the sigmoid is lower than described by the Henderson-Hasselbalch equation. To estimate the midpoint at which the contribution of $k_{obs1}$ and $k_{obs2}$ to reduction is equal, the data were fit to a sigmoidal curve with the slope as a variable, yielding a midpoint of pH 6.9.

Isoleuconol-binding studies

---

 iso eugenol-binding studies To evaluate whether the introduced mutations affect the protonation state of phenolic compounds bound to VAO, we studied the binding of the competitive inhibitor isoeugenol to
the VAO variants. In solution, the phenolic hydroxyl group of isoeugenol has a $pK_a$ of $\sim 10$ and its absorption spectrum is dependent on its protonation state (2). In particular, deprotonated isoeugenol displays significantly higher absorption at 320 nm than protonated isoeugenol ($\epsilon_{320} = 0.21 \text{ M}^{-1} \text{ cm}^{-1}$ at pH 6 and 8.8 $\text{ M}^{-1} \text{ cm}^{-1}$ at pH 12). Therefore, the absorption of isoeugenol at 320 nm upon binding to VAO can act as a reporter on its protonation state. The $pK_a$ of isoeugenol bound to wt-VAO is $\sim 5$ (2). To evaluate whether this has been perturbed by the introduced mutations, the VAO variants were titrated with isoeugenol at pH 7.5. At this pH, isoeugenol is almost entirely protonated in solution, but almost entirely deprotonated when bound to wt-VAO.

Spectral changes observed upon titration of wt-VAO with isoeugenol are shown in Fig. 5. Upon addition of isoeugenol, the intensity of the absorption peak of oxidized FAD at 439 nm decreases, whereas the absorption at wavelengths below 335 nm increases, which is due to the absorption of the added isoeugenol. Plots of the absorption at 439 and 320 nm against the concentration of isoeugenol displayed a curvature indicative of a binding event (Fig. 5, inset). The data at each of these wavelengths could be satisfactorily fit to a model assuming a simple 1:1 complex formation between isoeugenol and VAO. This yielded a dissociation constant of 6.8 ± 0.5 $\mu$M from the data at 439 nm and 6.8 ± 1.0 $\mu$M from the data at 320 nm. The increase in the absorption at 320 nm associated with binding of isoeugenol to VAO is indicative of the fact that, as expected, it is primarily in its deprotonated form upon binding to the enzyme.

Somewhat different spectral changes were observed upon titration of the Y108F variant with isoeugenol (Fig. 5). As with wt-VAO, the intensity of the peak at 439 nm decreases and absorption below 335 nm increases. In addition, a broad absorption band appears at wavelengths between 500 and 680 nm. Such a broad absorption band at high wavelengths is indicative of a charge-transfer interaction between isoeugenol and FAD, likely caused by $\pi$-stacking of the aromatic rings of isoeugenol and isoalloxazine. Similar charge-transfer bands have been observed upon binding of various aromatic compounds to the flavoprotein subunit of PCMH (12). Fitting of the data at 439 nm yielded a dissociation constant of 18 ± 2 $\mu$M, suggesting binding of isoeugenol is slightly impaired in the Y108F variant as compared with wt-VAO. The absorption at 550 nm also displayed curvature indicative of a single binding event and fitting yielded a dissociation constant of 20 ± 1 $\mu$M. This suggests that the drop in absorption at 439 nm and charge-transfer band at wavelengths above 500 nm are both caused by the same binding event, the formation of a 1:1 complex between isoeugenol and Y108F. The absorption at 320 nm, however, did not display the major increase associated with binding to wt-VAO. This suggests that isoeugenol is primarily in its protonated form when bound to Y108F and that the protonated form of isoeugenol forms a charge-transfer complex with the FAD cofactor of Y108F.

Figure 4. pH dependence of the contribution of $k_{\text{obs1}}$ to the reduction of 10 $\mu$M wt-VAO by 50 $\mu$M chavicol. Anaerobic substrate and enzyme solutions in Brit-¡Robinson buffers of appropriate pH values were mixed in a stopped-flow apparatus and absorbance changes were monitored using a photodiode array detector. Fitting curves to the absorbance at 440 nm yielded two reduction rates: $k_{\text{obs1}}$ (fast) and $k_{\text{obs2}}$ (slow). The graph shows the fraction of the drop in absorbance associated with reduction that is contributed by $k_{\text{obs1}}$ (fraction $k_{\text{obs1}} = \sigma \sigma_1 \sigma_2 + \sigma_3$, where $\sigma$ is the amplitude). The solid line is a fit of a sigmoidal function to the data, from which a midpoint pH value (fraction $k_{\text{obs1}} = 0.10$) of 6.9 was estimated. The inset shows the values of $k_{\text{obs1}}$ (A) and $k_{\text{obs2}}$ (D). The error on each data point is less than 5%.

With Y108F/Y503F, the results of the titration strongly resemble those with Y108F (Fig. 5). Dissociation constants of 11 ± 1 and 7.0 ± 0.4 $\mu$M were obtained by fitting to the data at 439 and 550 nm, respectively. The appearance of a charge-transfer band is observed and the absorption at 320 nm does not show the large increase associated with binding to wt-VAO. This suggests that, like for the Y108F and Y503F variants, isoeugenol is predominantly in its protonated form when in complex with Y108F/Y503F.

Crystal structures

To evaluate the effects of the mutations on the architecture of the active site of VAO, the crystal structures of the Y108F and Y503F variants were solved at 2.8-Å resolution, by molecular replacement using the VAO monomer (PDB code 2VAO) (4) as a search model. Attempts to solve the structure of the Y108F/Y503F variant were hampered by fragility of the crystals. The overall structures of both Y108F and Y503F are essentially identical to that of wt-VAO, as indicated by an r.m.s. deviation of 0.5 Å for 1105 and 1108 pairs of Ca atoms, respectively. The asymmetric unit contains two monomers, which form the functional octamer through crystallographic symmetry, as in wt-VAO.

The geometry of the active site in the mutated enzymes is largely conserved, with the aromatic ring of Phe-108 or Phe-503 located at the same position as the corresponding tyrosine residue in wt-VAO, where they each form a hydrogen bond with the phenolic hydroxyl group of isoeugenol (Fig. 2) (4). Additionally, Tyr-108 interacts with Ser-426 via a hydrogen bond. This interaction is disrupted in the Y108F variant, causing a...
shift of the Phe-108 side chain toward the FAD cofactor (Fig. 2B). In the Y503F variant, the plane of the aromatic ring of Phe-503 is slightly tilted compared with Tyr-503 in wt-VAO (Fig. 2C). This may partly be due to the lack of the hydrogen bond between Tyr-503 and Arg-504 that is present in wt-VAO.

In summary, both overall structures of the Y108F and Y503F variants and the geometry of their active sites are extremely similar to wt-VAO. Therefore, changes in reactivity are not due to major structural perturbations, but can be attributed to disruption of the hydrogen bonding capacity conferred by the two tyrosine residues.

Conservation of the phenolate-binding pocket in VAO homologues

To determine whether the residues that form the phenolate-binding pocket in VAO are also present in homologous proteins, we evaluated their conservation in a group of homologues of VAO, EUGO, PCMH, and the related flavocytochrome eugenol hydroxylase from *Pseudomonas* sp. OPS1 (13) that we identified in a previous study and named the 4-phenol oxidizing (4PO) subfamily (14). Additionally, we determined whether they are present in the decarboxylases CndG and FeeG, which catalyze the oxidative decarboxylation of *N*-substituted tyrosine derivatives (15, 16). These enzymes display homology to 4PO subfamily members and catalysis is believed to proceed via a mechanism whereby the initial formation of a para-quinone methide intermediate is followed by the expulsion of carbon dioxide. This analysis revealed that Tyr-108, Tyr-503, and Arg-504 are strictly conserved suggesting they are of importance for catalysis in these related enzymes.

Discussion

Our results demonstrate that the presence of at least one of the active site tyrosine residues, Tyr-108 or Tyr-503, is essential for efficient catalysis by VAO, with the $k_{cat}$ values for Y108F/ Y503F being less than 2% of those for wt-VAO for each tested substrate. The effect of the single tyrosine to phenylalanine mutations on catalytic efficiency was dependent on the substrate. The oxidation of vanillyl alcohol was severely impaired in both the Y108F and Y503F variants, whereas the oxidation of chavicol was only slightly impaired as compared with wt-VAO.

Stopped-flow kinetics revealed that reduction of the FAD cofactor of VAO by vanillyl alcohol or chavicol proceeds at two distinct rates: $k_{obs1}$ (fast) and $k_{obs2}$ (slow). $k_{obs2}$ lies close to the rate of steady-state catalysis and, therefore, is probably rate-limiting. The observed reduction in the rate of steady-state catalysis for the tyrosine to phenylalanine variants corresponds with the observed reduction in $k_{obs2}$ demonstrating that impaired flavin reduction is the cause of the reduced rate of catalysis. Titration with the competitive inhibitor isoeugenol indicated that, at pH 7.5, this molecule is predominantly in its deprotonated phenolate anion form when bound to wt-VAO, but predominantly in its protonated form when bound to Y108F, Y503F, or Y108F/Y503F. In combination, these results...
suggest that Tyr-108 and Tyr-503 play a role in activating the substrates of VAO for their reaction with its FAD cofactor by enabling their deprotonation in the active site of the enzyme. Interestingly, the relative contributions of the two reduction rates, $k_{\text{obs1}}$ and $k_{\text{obs2}}$, to the change in absorption associated with flavin reduction changes upon the introduction of the tyrosine to phenylalanine mutations. At pH 7.5, $k_{\text{obs1}}$ contributes more to the drop in absorption in wt-VAO, whereas in the Y108F, Y503F, and Y108F/Y503F variants, $k_{\text{obs2}}$ contributes more to the drop in absorption. The relative contributions of the two rates shift when the reduction is performed at pH 6.2, with the relative contribution of $k_{\text{obs2}}$ becoming greater. The reduction of the Y108F/Y503F variant by chavicol was an exception to this observation. However, this may be due to the contribution of $k_{\text{obs2}}$ to the reduction at pH 6.2 being underestimated due to the concomitant formation of a charge-transfer interaction between the reduced enzyme and substrate. For the reduction of wt-VAO by chavicol, the contribution of $k_{\text{obs1}}$ increases with pH in the pH range 6.1–9.5. The data were fit to a sigmoidal curve with a midpoint pH, at which $k_{\text{obs1}}$ and $k_{\text{obs2}}$ contribute equally to the reduction, of 6.9.

Based on these results, we propose a somewhat modified model for the reaction mechanism of VAO (Fig. 6). Substrates can bind in the active site of VAO with their phenolic hydroxyl group either in its protonated or deprotonated form. The affinity of the enzyme for the substrate depends on the protonation state of the substrate, with wt-VAO displaying a higher affinity for deprotonated substrates. Subsequently, the substrate reacts with VAO, a reaction that occurs at different rates depending on the protonation state of the substrate. With the deprotonated substrate, the reaction simply involves the transfer of a hydride anion to the FAD cofactor to yield the para-quinone methide intermediate. Reaction with the protonated substrate requires the deprotonation of the phenolic hydroxyl group of the substrate either prior to or at the same time as the hydride-transfer reaction. The proton is transferred to either Tyr-108 or Tyr-503, which may be transiently deprotonated in the active site of the enzyme. This is stimulated by Arg-504, which is positioned so as to form a cation–π interaction with Tyr-108, lowering its $pK_a$. This model explains the two rates of flavin reduction observed for each substrate, with $k_{\text{obs1}}$ representing the reaction with deprotonated substrate and $k_{\text{obs2}}$ representing the reaction with protonated substrate. This is supported by the fact that the contribution of $k_{\text{obs1}}$ to flavin reduction increases with pH, as at higher pH values a larger percentage of the substrate is in its deprotonated form. The results of the isoeugenol titrations support the idea that substrates bind to Y108F, Y503F, and Y108F/Y503F predominantly in their protonated form at pH 7.5, as opposed to wt-VAO where it predominantly binds in its deprotonated form. This explains the change in the relative contributions of $k_{\text{obs1}}$ and $k_{\text{obs2}}$ to flavin reduction upon introduction of the tyrosine to phenylalanine mutations. The mutations prevent the preferential binding of the deprotonated form of the substrates observed with wt-VAO due to the loss of hydrogen-bonding interactions that stabilize the negative charge on the phenolate oxygen. In support of this, the crystallographic analysis revealed that, although the mutations do not produce any major structural perturbation of the active site architecture, they modify the hydrogen-bonding network that is essential to activate the substrate for the reaction with the flavin cofactor. The fact that the curve of the fractional contribution of $k_{\text{obs1}}$ to the reduction versus pH does not obey the Henderson-Hasselbach equation may be attributable to the effects of functional groups near the phenolic hydroxyl group on its protonation state, which can have a distorting effect on the titration behavior of ionizable groups in proteins (17). Additionally, interconversion of the enzyme-protonated substrate ($E_{\text{ox}}–SH$) and enzyme-deprotonated substrate ($E_{\text{ox}}–S^-$) complexes may involve more significant changes than simply the deprotonation of the phenolic hydroxyl group of the substrate. The fact that a charge-transfer interaction is observed between the enzyme and protonated isoeugenol during titrations with this molecule, but not between the enzyme and deprotonated isoeugenol, suggest that the ligand may bind to the enzyme in a slightly different conformation depending on its protonation state. Thus conversion of the $E_{\text{ox}}–SH$ complex to the $E_{\text{ox}}–S^-$ complex may require a reorientation of the substrate within the active site, and possibly minor changes in the conformation of active site residues. This could explain the reasonably low rates observed for $k_{\text{obs2}}$. Although in our view this model provides the most satisfactory explanation of our observations, an alternative mechanism where the two observed reduction rates reflect the presence of two forms of the enzyme, one in which both Tyr-108 and Tyr-503 are protonated and one in which one of the two tyrosine residues is deprotonated, cannot be fully ruled out.

The effect of the single Y108F and Y503F mutations on the rate of reduction of VAO was dependent on the substrate used. With the benzylic alcohol vanillyl alcohol, a far more severe drop in both $k_{\text{obs1}}$ and $k_{\text{obs2}}$ was observed than with the 4-allylphenol chavicol. However, the change in the relative contributions of $k_{\text{obs1}}$ and $k_{\text{obs2}}$ to flavin reduction is similar. Possibly, the large effect on the reduction rate seen with vanillyl alcohol is due to incorrect positioning of the substrate in the active site of Y108F and Y503F. Hydrogen bonds between the phenolic hydroxyl group of the substrate and the two tyrosine residues may be of importance in maintaining it in the correct orientation for the hydride-transfer reaction to take place. This effect may be less important for chavicol than for vanillyl alcohol, as interactions involving its longer side chain may lock it into position in the active site. In this context, it is interesting to note
that the $K_m$ for the oxidation of chavicol by wt-VAO is significantly lower than that for the oxidation of vanillyl alcohol, indicating tighter binding of chavicol.

In addition to the 4PO subfamily members mentioned above, a catalytic motif composed of two tyrosine residues has been proposed to be involved in substrate activation in other enzymes in which catalysis occurs through a para-quinone methide intermediate, such as the cofactor-independent hydroxycinnamoyl-CoA hydratase-lyase from *Pseudomonas fluorescens* AN103 (18) and bacterial phenolic acid decarboxylases (19) (although an alternative mechanism has also been proposed (20, 21)). This suggests that these structurally unrelated proteins have obtained similar mechanisms for the activation of the phenolic hydroxyl groups of their substrates through convergent evolution.

Catalytic motifs composed of two tyrosine residues have also been implicated in substrate activation in a number of enzymes that catalyze oxidation reactions that do not involve a para-substituted phenol. They have been proposed to facilitate the activation of hydroxyl groups for their oxidation to carboxyls in other oxidoreductases from the VAO/PCMH family, such as aclacinomycin oxidoreductase from *Streptomyces galilaeus* ATCC 31615 (22), Dbv29 from *Nonomuraea* sp. ATCC 39727 (23), GilR from *Streptomyces griseoflavus* (24), and the monolignol oxidoreductase BBE-like protein 15 from *Arabidopsis thaliana* (25). These enzymes all belong to the same clade of the VAO/PCMH family, which primarily contains enzymes with a bicovalently bound FAD cofactor (26). Despite their homology with VAO, a sequence and structural alignment of the five pro-

### Analytical methods

Unless specified otherwise, all experiments were performed in 50 mM potassium phosphate buffer, pH 7.5. Absorption spectra of purified proteins were recorded using a Hewlett Packard 8453 photodiode array spectrophotometer (Agilent Technologies, Santa Clara, CA) and enzyme concentrations were determined using the extinction coefficient of wt-VAO at 439 nm ($\epsilon_{439} = 12,500 \text{ M}^{-1} \text{ cm}^{-1}$ (1)). For trichloroacetic acid precipitations, 5% (w/v) trichloroacetic acid was mixed with 10 μM enzyme and samples were incubated on ice for 30 min. Subsequently, the precipitated protein was pelleted by centrifugation (21,000 × g, 15 min, 4°C), and the presence of FAD in the pellet or supernatant was judged from its color. The absence of FAD from the supernatants was confirmed by measuring their absorption spectra. Analytical gel filtration was performed using a Superdex 200 HR 10/30 column on an Äkta pure chromatography system (GE Healthcare). Samples of enzyme at a concentration of 10 μM were loaded onto the column and subsequently eluted in 50 mM potassium phosphate buffer, pH 7.5, containing 150 mM potassium chloride. Molecular masses were determined based on a calibration curve of proteins of known mass. Thermal unfolding of the VAO variants was monitored by the ThermoFAD method (11) using a MiniOpticon real-time PCR system (Bio-Rad). Protein solutions at a concentration of 7 μM were subjected to a temperature gradient from 25 to 70 °C and the fluorescence of the FAD cofactor was measured every 0.5 °C with excitation and emission wavelengths of 485 ± 30 and 625 ± 30 nm, respectively. Thermal midpoints of unfolding were determined by finding the maximum of the derivative of the unfolding curves.

### Steady-state kinetics

All experiments were performed at 25 °C in 50 mM potassium phosphate buffer, pH 7.5. The oxidation of vanillyl alcohol to vanillin was followed by monitoring the absorption of the product at 340 nm ($\epsilon_{340} = 14,000 \text{ M}^{-1} \text{ cm}^{-1}$). The oxidation of chavicol was followed by monitoring oxygen consumption using a Hansatech Oxytherm system (Hansatech Instruments, King’s Lynn, UK). Steady-state kinetic parameters were determined by fitting the obtained data to the Michaelis-Menten equation (vanillyl alcohol) using IGOR Pro (Wavemetrics, Lake Oswego, OR) or to a modified version of the Michaelis-Menten equation that includes a term to take substrate inhibition into account (chavicol),

$$k_{\text{obs}} = \frac{k_{\text{cat}} [S]}{K_m + [S] + \frac{[S]^2}{K_i}}$$  
(Eq. 1)
where $k_{\text{obs}}$ is the measured initial rate, $k_{\text{cat}}$ is the turnover number, $K_m$ is the Michaelis constant, $K_i$ is the inhibition constant for substrate inhibition, and $[S]$ is the substrate concentration.

**Stopped-flow kinetics**

The reduction of VAO variants by vanillyl alcohol or chavicol was followed using an SX20 stopped-flow system (Applied Photophysics, Leatherhead, UK) equipped with a photodiode array detector or a photomultiplier detector as applicable. Enzyme and substrate solutions in 50 mM potassium phosphate buffer, pH 6.2 or 7.5, as appropriate, containing 5 mM glucose were made anaerobic by first flushing them with nitrogen gas for 10 min and then adding 0.3 μM glucose oxidase. Subsequently, the enzyme and substrate solutions were mixed to final concentrations of 10 μM enzyme and 2 mM (vanillyl alcohol) or 100 μM (chavicol) substrate and spectral changes were monitored at 25 °C. Rate constants were obtained by global fitting of multiple single wavelength traces to appropriate exponential functions using IGOR Pro. Spectral deconvolution of mult wavelength data were performed using Pro-Kineticist (Applied Photophysics). To study the pH dependence of the reduction of wt-VAO by chavicol in more detail, the reaction was performed at various pH values in the pH range 6.1–9.5. Experiments were performed in Britt-Robinson buffers consisting of 40 mM sodium acetate buffer, pH 4.6, and cryo-cooled in liquid nitrogen.

**Isoeugenol-binding studies**

Changes in the spectral properties of the VAO variants upon binding of the competitive inhibitor isoeugenol were monitored using a Cary 4000 spectrophotometer (Agilent Technologies, Santa Clara, CA). Isoeugenol was titrated to 10 μM enzyme in 50 mM potassium phosphate buffer, pH 7.5, and an absorption spectrum was recorded after every addition. Dissociation constants were determined by fitting the data at a specific wavelength to a model assuming formation of a 1:1 enzyme–isoeugenol complex using the following formula with IGOR Pro,

$$A = \epsilon_{\text{e}} \times [E]_f + \epsilon_{\text{EI}} \times [EI] + \epsilon_{\text{i}} \times [I]_f \quad \text{(Eq. 2)}$$

where

$$[EI] = [I]_f + [E]_f + K_d - \sqrt{([E]_f + [I]_f + K_d)^2 - 4 \times [I]_f \times [E]_f} \quad \text{(Eq. 3)}$$

and

$$[E]_f = [E]_f - [EI] \quad \text{(Eq. 4)}$$

with $\epsilon_{\text{e}}$, $\epsilon_{\text{EI}}$, and $\epsilon_{\text{i}}$ being the molar extinction coefficients of the free enzyme, the enzyme-inhibitor complex, and the free inhibitor, respectively, $[E]_f$ being the concentration of free enzyme, $[EI]$ the concentration of enzyme-inhibitor complex, $[I]_f$ the concentration of free inhibitor, $[E]_f$ the total enzyme concentration, $[I]_f$ the total inhibitor concentration, and $K_d$ the dissociation constant.

**Crystallization and structure determination**

VAO variants were crystallized by the hanging drop vapor diffusion method. Protein solutions at a concentration of 180–220 μM in 50 mM potassium phosphate buffer, pH 7.5, were mixed 1:1 (v/v) with a mother liquor containing 6% (w/v) PEG4000 and 20% (w/v) glycerol in 100 mM sodium acetate buffer, pH 4.6, and cryo-cooled at 20 °C. Prior to data collection, crystals were transferred to a cryoprotectant solution containing 10% (w/v) PEG4000 and 20% (w/v) glycerol in 100 mM sodium acetate buffer, pH 4.6, and cryo-cooled in liquid nitrogen. X-ray diffraction data were collected at the X06DA beamline of the Swiss Light Synchrotron in Villigen, Switzerland (SLS), and at the ID30B beamline of the European Synchrotron Radiation Facility in Grenoble, France (ESRF). Images were integrated using MOSFLM (28) and data were scaled using programs of the CCP4 suite (29). Detailed data processing statistics are shown in Table 4. Structures of VAO mutants were solved by molecular replacement using PHASER (30) with the structure of wt-VAO (PDB code 2VAO (4)) devoid of all ligands and water molecules as a search model. Subsequently, structures were refined by alternating refinement using REFMAC5 (31) and manual model building using COOT (32). Figures were prepared with CCP4mg (33).

### Table 4

| Data collection and refinement statistics | Y108F | Y503F |
|-----------------------------------------|-------|-------|
| PDB code                                | SMXJ  | SMXU  |

| R.m.s. bond angles (°)                  | 1.56  | 1.48  |

* Data processing statistics was based on CC1/2 as described in Refs. 34 and 35.
* $R_{\text{free}} = \Sigma |F_{\text{obs}} - F_{\text{calc}}|/\Sigma F_{\text{calc}}$, where $F_{\text{obs}}$ and $F_{\text{calc}}$ are the observed and calculated structure factor amplitudes, respectively. $R_{\text{cryst}}$ and $R_{\text{warp}}$ were calculated using the working and test sets, respectively.
Substrate activation in VAO

the Protein Data Bank under the PDB ID codes 5MXJ (Y108F-VAO) and 5MXU (Y503F-VAO).

Author contributions—T. A. E. and W. J. H. B. conceived the study and designed the experiments. T. A. E. and R. C. A. performed the expression, purification, and biochemical characterization of the VAO variants. T. A. E. and Q. T. N. performed the crystallization and solved the structures of the VAO variants. A. M. and C. B. supervised this part of the study. T. A. E. performed the stopped-flow kinetics measurements. E. R. and M. W. F. supervised this part of the study. G. G. performed the bioinformatic analysis. All authors contributed to analyzing the data and writing the paper.

Acknowledgments—We thank the European Synchrotron Radiation Facility (ESRF) and the Swiss Light Source (SLS) for providing beam time and assistance and the European Community’s Seventh Framework Programme (FP7/2007–2013) under BioStruct-X (Grants 7551 and 10205) for funding synchrotron trips.
