Background: Total knee replacement is often accompanied by severe post-operative pain. Oxycodone has sufficient analgesic effects and somewhat greater, but tolerable side effects compared to fentanyl. However, most studies on the topic evaluate visceral pain relief. In this study, we determine the effectiveness of oxycodone for somatic pain and evaluate the incidence of side effects.

Methods: Sixty-nine patients were involved in a randomized control trial. Analgesic agents were administered to two experimental groups at a post anesthetic care unit (PACU) 15 min after PACU admission: a 50 µg fentanyl group (n = 40) and a 4 mg oxycodone group (n = 29), both with severe pain (numeric rating scale, NRS > 5). Changes in NRS at the PACU were measured. Additional analgesic agents were administered at 0–6, 6–12, 12–24, and 24–48 h after surgery.

Results: Total fentanyl consumption and the number of patients who required additional opioids were significantly lower in the oxycodone group than in the fentanyl group. Incidence of side effects was not significantly different between the two groups.

Conclusions: Oxycodone shows a better analgesic effect than fentanyl in somatic pain in the acute phase of post-operative pain. The side effects of oxycodone are not significantly different from those of fentanyl. (Anesth Pain Med 2016; 11: 349-353)

Key Words: Oxycodone, Post-operative pain, Total knee replacement.

INTRODUCTION

Post-operative pain management is an important factor in improving quality of life during hospital stays for total knee replacement (TKR) patients [1]. Opioids are known to be effective for post-operative pain control. Morphine and fentanyl are commonly used opioids, but there is a lack of research on oxycodone’s potential as a suitable replacement for fentanyl [2]. Oxycodone is a strong, pure, and semisynthetic opioid that acts as an agonist of the central, peripheral, and autonomous nervous systems. There are several studies of its efficacy and safety in treating both acute and chronic moderate-to-severe post-operative or cancer pain without ceiling effects [3-6]. Oxycodone can be administered through many routes: intravenous [7,8], intramuscular [9], rectal [10], subcutaneous [11], intranasal [8], epidural [12], and oral [9].

There are several studies suggesting that oxycodone has a comparable analgesic effect and somewhat greater, but tolerable side effects compared to fentanyl as an adjunctive drug [13-15]. However, most of the studies evaluated visceral pain relief.

In this study, we investigated whether oxycodone is an effective substitute for fentanyl for early post-operative pain management in orthopedic surgery. We also compared possible side effects in both groups.

MATERIALS AND METHODS

A prospective, randomized controlled trial and single-blind study was conducted, and patients were given informed consent before surgery. Patients with a history of hepatitis and renal failure, habitual drug use, mental illnesses, and side effects for...
previous opioid history were excluded from the study. Eighty-two patients were scheduled for total knee replacement. Patients were randomly divided into two groups using Excel (Microsoft Corp., Korea): a group receiving 50 \( \mu \)g fentanyl (Group F, \( n = 40 \)) and a group receiving 4 mg oxycodone (Group O, \( n = 29 \)). Diagrams of each group are presented in Fig. 1. After screening, a total of 69 patients designated as American Society of Anesthesiologists physical status class I to II were included in this study. We used the numerating scale (NRS) calculation method (NRS; 0 = no pain, and 10 = most severe pain) for measuring pain severity.

A standardized, general anesthetic technique was used for each patient. In the operating room, all patients were continuously monitored with electrocardiography, pulse oximetry, bispectral index, blood pressure, and capnography. We administered glycopyrrolate 0.2 mg and palonosetron 0.075 mg for premedication. Anesthesia was induced with 1-2 mg/kg propofol and 0.8 mg/kg rocuronium. Desflurane (5-7 vol%) was used with a mixture of nitrous oxide (50%) and oxygen (50%) for anesthesia maintenance. Remifentanil was also infused at 1.5-5.0 \( \mu \)g/min. Fifteen minutes before the end of surgery, 50 \( \mu \)g of fentanyl bolus was administered. Following full skin closure, desflurane and remifentanil were discontinued. The reversal agent was mixture of 0.4 mg glycopyrolate and 15 mg pyridostigmine. Tracheal extubation was performed after self-respiration was recovered and the patient’s eyes opened. All patients received intravenous patient-controlled analgesia (IV PCA) with 15 \( \mu \)g/kg fentanyl for 2 days (0.31 \( \mu \)g/kg/h). Additional intravenous fentanyl bolus was used instead of pushing a PCA bolus button in the postoperative period.

After surgery was complete, patients were transferred to the post anesthetic care unit (PACU), and observed for at least 30 min before being transferred to the general ward. In a double-blind manner, the analgesic agent (either 50 \( \mu \)g fentanyl or 4 mg oxycodone) was administered depending on whether the patient’s NRS exceeded 5, and we assessed the NRS 15 min later. Additionally, the patient’s post-operative nausea and vomiting (PONV), dizziness, pruritus (itching), headache, respiratory depression, and sedation grade (awake and alert, occasionally drowsy, easily aroused, asleep) in the PACU were all observed.

In the general ward, if patients requested more pain relief, 50 \( \mu \)g of fentanyl were administered. The time of the first administration of analgesia was monitored, as was total fentanyl

consumption via intravenous bolus and PCA during the periods of 0–6, 6–12, 12–24, and 24–48 h after surgery.

The primary endpoint was the difference in fentanyl consumption during the acute postoperative period (0–6 h). Based on a pilot study, the difference and standard deviation between the two groups were expected to be 25 and 29 μg, respectively. The sample size was calculated using SigmaPlot 13.0 (Systat Software Inc., USA). The minimum sample size required in each group with a significance criterion (α) of 0.05 and a statistical power of 0.8 was 23. All statistical analyses were carried out using SPSS software (version 21.0, IBM Corp., USA). Mann-Whitney U tests or unpaired t-tests were performed to compare continuous variables between the two groups. Discrete variables, side effects, and the proportion of patients who required additional opioids were analyzed using the Chi-square test. P value less than 0.050 was considered statistically significant. Data are presented as the mean ± SD deviation unless otherwise noted.

**RESULTS**

The study involved 69 patients. Demographic and clinical characteristics of the patients organized according to group are shown in Table 1. There were no statistically significant differences between the two groups in patient age, weight, height, duration of surgery, and total remifentanil consumption (P > 0.050)

Total fentanyl consumption during the periods of 0–6, 6–12, 12–24, and 24–48 h after surgery was calculated. Significantly less fentanyl was consumed in Group O compared to Group F (P < 0.050) during each of the time periods (Fig. 2).

The proportion of patients who required additional opioids was also counted during the periods of 0–6, 6–12, 12–24, and 24–48 h after surgery (Table 2). A significantly lower proportion was observed in Group O than in Group F during 0–6 and 12–24 h.

Pain scores before and after administration of analgesics (Table 3) did not differ significantly between the two groups

| Table 1. Demographic Data and Anesthesia Characteristics |
|---------------------------------------------------------|
| **Group F** | **Group O** |
| (n = 40)    | (n = 29)    |
| Age (yr)    | 69.4 ± 5.1 | 71.2 ± 7.0 |
| Weight (kg)| 60.1 ± 8.6 | 59.6 ± 9.0 |
| Height (cm)| 152.0 ± 5.7| 152.4 ± 8.2|
| Duration of surgery (min) | 173.5 ± 44.5 | 168.8 ± 44.0 |
| Total remifentanil consumption (μg) | 289.2 ± 74.2 | 281.3 ± 73.2 |

Values are the mean ± SD. Group F: intravenous administration of 50 μg fentanyl at post-anesthetic care unit (PACU). Group O: intravenous administration of 4 mg oxycodone at PACU.

| Table 2. Patients Number which Require Additional Opioid |
|---------------------------------------------------------|
| **Time after surgery (h)** | **Group F** | **Group O** | **P value** |
| (n = 40)    | (n = 29)    |            |
| 0–6        | 20 (50.0%) | 6 (20.7%)  | 0.012       |
| 6–12       | 16 (40.0%) | 8 (27.6%)  | 0.209       |
| 12–24      | 27 (67.5%) | 11 (37.9%) | 0.014       |
| 24–48      | 22 (55.0%) | 13 (44.8%) | 0.278       |

Values are number of patients (%). Group F: intravenous administration of 50 μg fentanyl at post-anesthetic care unit (PACU). Group O: intravenous administration of 4 mg oxycodone at PACU.

| Table 3. NRS while in PACU |
|-----------------------------|
| NRS (1–10) | **Group F** | **Group O** | **P value** |
| (n = 40)    | (n = 29)    |            |
| NRS before analgesics administration (1–10) | 6.0 ± 0.6 | 6.2 ± 0.8 | 0.189       |
| NRS after 15 min (1–10) | 3.0 ± 0.4 | 3.1 ± 0.8 | 0.507       |
| NRS differences (1–10) | 3.0 ± 0.8 | 3.1 ± 0.9 | 0.537       |

Values are the mean ± SD. Group F: intravenous administration of 50 μg fentanyl at post-anesthetic care unit (PACU). Group O: intravenous administration of 4 mg oxycodone at PACU. NRS: numeric rating score.
Opioids are widely used for post-operative pain management; these include morphine, the fentanyl series, oxycodone, pethidine, etc. Oxycodone is a semisynthetic opioid derived from thebaine, and acts as an agonist on mu, kappa, and delta receptors in the central nervous system. The plasma half-life of thebaine, and acts as an agonist on mu, kappa, and delta receptors in the central nervous system. Oxycodone is a semisynthetic opioid derived from thebaine, and acts as an agonist on mu, kappa, and delta receptors in the central nervous system. It has been shown to provide almost immediate analgesic effects when administered intravenously, whereas oxycodone takes 3–5 h, with stable plasma concentration levels reached within 24 h [16].

Most studies on the pain control abilities of oxycodone involve PCA infusion in the ward [14,15,17]; there are few studies in the PACU. In addition, oxycodone is known to be effective for visceral pain, thus studies are focused solely on visceral pain [13]. Therefore, we studied whether oxycodone is an effective analgesic agent for somatic pain as well.

TKR is often accompanied by severe post-operative pain. Post-operative pain is the most common reason for delayed rehabilitation, prolonged hospital stays, and chronic pain after a TKR [17]. In the acute postoperative phase, most patients reported severe pain (NRS 6–7) in this study despite PCA infusions. Severe acute pain is likely to lead to chronic pain [13], so in the PACU, adequate and prophylactic pain management is necessary. In this study, the oxycodone group showed lower fentanyl consumption not only during the 0–6 h post-operative period but also the 6–48 h period. Therefore, we conclude that oxycodone is a suitable analgesic for management of acute postoperative pain.

While IV oxycodone is known to be equipotent to morphine, it is reported that the potency ratio of fentanyl to morphine is 1:80–100 [10]. In addition, Herrick et al. [18] compared IV PCA (fentanyl) with IV PCA (morphine) in TKR patients and concluded that the fentanyl group needed more PCA bolus but reported the same VAS score in fentanyl to morphine ratio 1:100. Hwang et al. [2] have suggested that the potency ratio of fentanyl to oxycodone is approximately 1:75 and that oxycodone might be more potent than morphine (4:3). Therefore, we administered fentanyl at 50 μg for fentanyl group and oxycodone at 4 mg for oxycodone group.

Analgesic effects were measured using NRS in the PACU. It appears that oxycodone has a longer analgesic effect than fentanyl, because the oxycodone group reported lower total fentanyl consumption and a lower proportion of patients who demanded additional opioids. Therefore, we conclude that oxycodone is more effective than fentanyl in the acute phase of post-operative pain control. In previous studies, fentanyl has been shown to provide almost immediate analgesic effects when administered intravenously, whereas oxycodone takes effect 10–15 min after administration [7,10]. Our study showed that the change in NRS between group F and group O was not different at 15 min.

Common side effects of oxycodone are constipation (around 25–30% of patients), nausea (25%), drowsiness (25%), dizziness (15%), vomiting (10–15%), and pruritus (10–15%) [16]. In this study, the higher incidence of PONV may be due to bolus opioids that were complementary to PCA. In addition, the occurrence of nausea after surgery may be due to other factors such as the impact of the effects of inhaled anesthetics and surgical pain [19]. Most nausea occurred within 24 h and showed a tendency to decrease over time in both groups. No patients reported dizziness or headache, while two people fell asleep but were easily aroused. However, there were no significant differences in side effects between two groups (P > 0.050).

There are several limitations in this study. The number of patients in the oxycodone group is lower than that in the fentanyl group. Furthermore, there is more missing data in group O than in group F. More balanced grouping will be
important in future studies. As mentioned previously, we administered 4 mg of oxycodone. However, Park et al. [14] suggested that a potency ratio of fentanyl to oxycodone of 1 : 60 is sufficient for an analgesic effect, while minimizing side effects. We should consider the overestimation of potency ratios because our patients used IV PCA in combination with fentanyl. Therefore, additional studies using various potency ratios will be needed. Although there is no need to reduce dose with age [16], we report that most patients were elderly and female. There is a need to conduct research with a broader patient population.

In conclusion, oxycodone shows better analgesic effects than fentanyl for acute somatic pain during the post-operative period. Side effects are not significantly greater than fentanyl. Thus, oxycodone is a reasonable choice as an alternative to fentanyl.
