Distributed Multi-Target Tracking in Camera Networks

Sara Casao\textsuperscript{1} \hspace{1em} Ana C. Murillo\textsuperscript{1} \hspace{1em} Eduardo Montijano\textsuperscript{1}

Abstract— Most recent works on multi-target tracking with multiple cameras focus on centralized systems. In contrast, this paper presents a multi-target tracking approach implemented in a distributed camera network. The advantages of distributed systems lie in lighter communication management, greater robustness to failures and local decision making. On the other hand, data association and information fusion are more challenging than in a centralized setup, mostly due to the lack of global and complete information. The proposed algorithm boosts the benefits of the Distributed-Consensus Kalman Filter with the support of a re-identification network and a distributed tracker manager module to facilitate consistent information. These techniques complement each other and facilitate the cross-camera data association in a simple and effective manner. We evaluate the whole system with known public data sets under different conditions demonstrating the advantages of combining all the modules. In addition, we compare our algorithm to some existing centralized tracking methods, outperforming their behavior in terms of accuracy and bandwidth usage.

I. INTRODUCTION

Multi-target tracking systems have a broad range of applications, such as security surveillance or crowd behavior analysis. Approaching these problems with multi-camera set ups brings additional features and benefits with respect to single camera systems, such as more complete information for large spaces or crowded scenes. Besides, multi-camera systems naturally lead to the development of distributed systems, which are lighter in communication demands, more robust to failures and faster in processing time than centralized ones.

However, the implementation of a multi-target multi-camera tracking in a distributed setup has several challenges. First, the construction of robust and efficient distributed systems in terms of bandwidth usage, consensus between nodes and selection of accurate information to share. Second, in the presence of multiple targets, each camera must solve independently a data association problem between measurements and trackers. In addition, in contrast with centralized systems, where the central node unifies the high level information returning it labeled to the nodes, in a distributed setup the data association across cameras is locally performed with partial information.

This work tackles the challenges discussed above by exploiting synergies between complementary modules typically studied independently in prior work. We present an approach for multi-target tracking in a distributed camera network boosting the implementation of a Distributed Kalman Filter (DKF), a local data association process that uses a state of the art re-identification network and a novel distributed method for high level information management. The overall idea is illustrated in Fig. 1. The DKF exploits the local data association to decide which information needs to be merged into the distributed consensus update. Similarly, the data association is enhanced with the uncertainty estimations given by the DKF. Finally, the tracker manager makes sure of correct association during the initialization and synchronized deletion of the lost trackers. The main trade-off to consider in our system is bandwidth usage vs accuracy, which we also handle with a careful design.

Specifically, our main contributions are:

- A DKF implementation augmented with fully automatic data association based on geometric cues and appearance information. Differently from existing integrated approaches, we run a single communication message per estimation cycle, lightening the process and increasing applicability to real world setups.

- A novel distributed strategy to manage the trackers’ information. In contrast with centralized systems, where the central node unifies the information, we propose a distributed data association across cameras that manages the partial information in local nodes. To minimize the excess of bandwidth usage caused by the exchange of appearance information, our algorithm requires appearance features communication only once per tracker.

The proposed approach is evaluated in challenging public benchmarks, demonstrating the benefits with respect to a naive DKF implementation, as well as established centralized
algorithms. Experimentation detailed in Section IV analyzes different relevant aspects including the effect of connectivity restrictions, the influence of appearance cues integration and the effects of our strategy to unify high level information.

II. STATE OF THE ART

This section summarizes related work on core multi-target multi-camera tracking aspects.

A. Multi-view multi-target tracking in centralized systems

Multi-target multi-camera tracking in centralized systems sends the information from each camera to a common location where all the data is processed together [1]. These implementations, which stand out for their accuracy, are typically used in safety applications [2], [3]. Obtaining the complete trajectories of several targets is normally formulated as an optimization problem in a graph. The nodes represent short trajectories, known as tracklets, obtained by the association of detected bounding boxes. There are different variations to compute the weights of the graph. The combination of the similarity measure given by a triplet loss with a linear motion model is proposed in [4]. The proposal in [5] is the association of tracklets across views based on correlations in motion, appearance, and the resulting 3D trajectory smoothness. A method is presented in [6] to select a subset of tracklets from the graph and associate them based on geometry and motion cues. Other works such as [7], model the tracklet association problem as a hierarchical structure optimization. The main disadvantages of centralized methods are the excessive bandwidth usage required to send all the information to the central computer and the lack of robustness with respect to a single point of failure.

B. Multi-view multi-target tracking in distributed systems

Distributed implementations typically focus on improving the robustness and the efficiency through the study of the bandwidth, the consensus between nodes and the accuracy of the information shared. Several algorithms are proposed in [8] to achieve a consensus in a distributed heterogeneous sensor network performing only one communication per cycle. One of those algorithms is implemented in [9] for a PTZ camera network to track people of interest, although the data association problem is not addressed there. The work in [10] selects the ICF method [11] as consensus algorithm and fills the gap of data association with the JPDAF algorithm [12], which uses the previous target states to relate measurements and trackers. A drawback of the ICF method is the use of several communication messages per camera and estimation cycle, being less efficient and partially breaking the appealing properties of pure distributed systems. Using the same consensus algorithm, [13] proposes a tracking approach in a distributed camera network. They address data association within each camera through a global metric, merging appearance and geometry cues, and across-view data association through the euclidean distance between the 3D position of the targets The improvement of the Consensus Kalman Filter is discussed in [14] posed as a Maximum A Posteriori (MAP) optimization problem. The algorithm consists of closed-form algebraic iterations that guarantees the convergence to the centralized MAP over a designated sliding time window. They assume that each target in the environment has a unique identifier known to all sensors. Our multi-target multi-camera tracking approach is based on [9], and fills the gap of automatic data association between measurements and trackers with a global metric based on geometry and appearance. Unlike the consensus algorithm in [13], the algorithm implemented in this work only performs one communication per estimation cycle, lightening the communication process. Besides, we include a specific strategy to manage the high level data across cameras to improve the global data association.

C. Data association and re-identification

A wide variety of techniques have been proposed to the problem of data association. One of the most popular is the use of motion models to compute similarity based on geometric constraints, and the use of features such as histograms for appearance criteria [15], [16]. Commonly, a global similarity function is defined based on both metrics. Other works such as [17] extract body poses and relate them by the nearest observation statistically consistent with the distribution of positions. Taking into account the factors included in the data association problem, [18] defines several costs related to geometry, shape, appearance, pose and coordinate transformation to obtain a complete similarity function. The work proposed in [19] uses inertial sensing and RGB-D cameras to capture the skeleton data and perform a short-term pairing. A long-term pairing process adds the color histogram to the similarity function in order to increase robustness. The data association process in our approach is similar to [15], but our implementation takes advantage of re-identification strategies supported by recent deep learning techniques. A generalized strategy is based on comparing feature vectors, obtained from a network output, to measure the similarity between a query image and a global gallery (i.e., model) of individuals [20], [21], [22]. In order to be efficient and effective, to extract these appearance feature vectors we use the architecture proposed in [23], that mixes global and local features in a lightweight network, changing traditional convolution operations by depth-wise operations.

III. DISTRIBUTED TRACKING APPROACH

Figure 2 summarizes the proposed architecture. First, image target positions are obtained with a standard person detector [24] in each camera. Then, the association between the current detections and existing trackers is performed locally (LDA). This association is based on a global score computed from the geometric cues provided by the local tracking filter and the appearance similarity with respect to the appearance model of the person tracked stored in the local gallery. To continue the cycle, each camera exchanges a single communication message with the neighboring cameras, the trackers get into the DKF where the new state of the target is updated and sent to the DTM block. Finally, DTM
the cylinder center, \( (\dot{x}, \dot{y}) \) are the velocity of the target in \( x \) and \( y \) directions. The filter models the motion of the target considering a discrete-time linear dynamical system,

\[
x(k+1) = A x(k) + w(k), \quad z(k) = H x(k) + v(k),
\]

where \( w(k) \) and \( v(k) \) are zero mean Gaussian noise \( \sim \mathcal{N}(0, Q(k)) \) and \( \sim \mathcal{N}(0, R(k)) \), being \( Q(k) \) and \( R(k) \) the model and measurement covariance matrices respectively. The change of the target model in each step depends directly on the transition matrix \( A \), which considers a constant velocity model on the target position and no dynamics on the rest of the state. The noisy measurement \( z(k) \) is the 3D cylinder obtained as the projection of the bounding box given by the detector, i.e., \( z(k) = (x(k), y(k), w(k), h(k)) \) plus the noise. To obtain this projection we assume known homographies to map the image plane to ground plane coordinates.

The independent execution of the filter in each camera, \( C_i \), produces a local estimation of the target, \( \bar{x}_i(k) \), possibly different to other cameras estimation. A Distributed Kalman-Consensus filter is used to mitigate these differences. The consensus algorithm works with known data association between the local measurement, \( z_i(k) \), and target prediction for all the cameras. From this association, each camera computes the vector and matrix information,

\[
u_i(k) = H^T R_i^{-1}(k) z_i(k), \quad U_i(k) = H^T R_i^{-1}(k) H.
\]

Both of them are sent to the neighboring cameras, together with the prediction of the target state, \( \bar{x}_i(k) \), obtained as \( \bar{x}_i(k) = A \bar{x}_i(k-1) \). Once the camera receives the information from its neighbors, \( C_j \), the parameters \( y_i(k) \) and \( S_i(k) \) are calculated with

\[
y_i(k) = \sum_{C_j \in C_i^n} u_j(k), \quad S_i(k) = \sum_{C_j \in C_i^n} U_j(k).
\]

The state is then updated by the correction in the prediction of the target state with the merged information and the predictions from the neighboring cameras,

\[
\bar{x}_i(k) = \bar{x}_i(k) + M_i(k) [y_i(k) - S_i(k) \bar{x}_i(k)] + \gamma M_i(k) \sum_{C_j \in C_i^n} (\bar{x}_j(k) - \bar{x}_i(k)),
\]

where \( P_i(k) \) is the covariance of the target state, \( M_i(k) = (P_i(k)^{-1} + S_i(k)^{-1})^{-1} \) is the Kalman Gain in the information form and \( \gamma = 1/\|M_i(k+1)\| \). Finally, the covariance matrix is updated according to \( P_i(k+1) = AM_i(k)A^T + Q_i(k) \).

Although the standard implementation of the DKF assumes synchronization of the cameras, the consensus-nature of the algorithm makes it amenable to a fully asynchronous, event-triggered implementation such as [25].

B. Local Data Association

In our method, the local data association required for a correct update of the filter is made merging two constraints based on geometry and appearance. Let us consider now that in a particular estimation cycle, the set of measurements \( Z = \{z_j \} \) is provided by the detector to the local data association module. Since the DKF keeps track of the uncertainty of the tracker state, we take advantage of this information to calculate the Mahalanobis distance between the \( x, y \) position on the ground of each measurement, \( z_j \), and the predicted position, \( \bar{x}_i \),

\[
d(z_j, \bar{x}_i) = \sqrt{(z_j - H \bar{x}_i)^T V^{-1}(z_j - H \bar{x}_i)^T},
\]

being \( V = P_{xy} + R_{xy} \), with \( P_{xy} \) and \( R_{xy} \) the sub-matrices of \( P \) and \( R \) that encode the position covariance. Then, the similarity value in geometry is computed as

\[
s_d(z_j, \bar{x}_i) = \left\{ \begin{array}{ll} \frac{1}{\alpha} d(z_j, \bar{x}_i) & \text{if } d(z_j, \bar{x}_i) < \tau \\ 1 & \text{otherwise,} \end{array} \right.
\]

where \( \alpha \) is a configuration parameter and \( \tau \) a threshold applied to ignore highly unlikely candidates.

The candidates selected by the geometry constraint are then evaluated in appearance. Instead of using traditional hand-crafted descriptors to measure the appearance similarity, we employ a network designed for people re-identification [23], whose weights have been pre-trained with the MSMT17 Benchmark [26]. Inspired by the re-identification task evaluation methodology, we associate with each tracker a local gallery of limited size that represents the target appearance model. The construction of this gallery is currently done by simply storing locally observed patches for each target and updating them over time, saving a new
patch every \( N \) frames, and discarding the oldest one. The appearance similarity between a query and the tracker gallery is obtained with the minimum cosine distance,

\[
s_q(a_j) = \min_{a_i \in A_i} \left( 1 - \frac{a_j^T a_i}{\|a_j\| \|a_i\|} \right),
\]

where \( a_j \), the query, is the appearance feature vector associated to detection \( z_j \), and \( A_i = \{a_i\} \) is the set of feature vectors of the target gallery used by camera \( C_i \). The final decision in the data association is based on selecting the minimum value of the product of both scores, \( s_a \) and \( s_d \).

C. Distributed Tracker Manager

Another important issue to address in a practical implementation of the DKF is the management of the trackers through the full distributed system. This requires a correct data association of trackers across different cameras to guarantee that the information mixed in (3) and (4) corresponds to the same target. Similarly, the cameras need to agree upon the time in which a particular tracker is no longer relevant and should be dropped. We propose how to address these problems in a distributed fashion.

Distributed Global Data Association: Trackers are identified locally by a two-dimensional unique identifier, \( ID_i \), described by the camera id in the network, \( i \), and a local counter, \( n \). New trackers can either be initialized because of a new local observation or because of a transmission from neighboring cameras.

Local initialization is done whenever a new target generates two observations in its local gallery. This helps filtering spurious measurements from the detector, giving enough time for a new tracker to ensure that it corresponds to a valid target. Once this happens, we attach to the DKF data the appearance model, \( A_{ID_i} \), in the message sent to neighbors. It is important to highlight that this is the only moment when appearance is transmitted through the network in our algorithm, consisting in the two descriptors available in the local gallery at that time.

The second case that can trigger new tracker initializations in our system is the reception of messages from neighboring cameras. Our algorithm considers three situations for this case: 1) A single neighbor camera sends a new tracker. Then, the camera creates a new tracker and associates it to the received one for the future DKF consensus updates. The local gallery is initialized with the appearance model received. 2) The camera receives new trackers from several neighboring cameras. 3) A new local tracker is initialized at the same time that new trackers from other cameras are received. In situations 2) and 3), it is necessary to check whether the new trackers from the different cameras are of the same target or not. We perform a similar process as the local data association described in III-B, replacing in (3) the measurement by the other camera’s estimation, \( d(\hat{x}_i, \bar{x}_j) \), and the Mahalanobis distance with the Euclidean distance, \( \sqrt{V} = I \), since the covariance matrices associated to the trackers are not part of the messages. This also requires a different threshold in (6). If two or more trackers are similar enough, they are merged locally into a single one.

Consensus-based Tracker Drop and Re-initialization: The other main task of the Tracker Manager is to decide when to drop a tracker. Instead of letting each camera decide this process individually, we have opted for a consensus-based solution that reduces, as much as possible, the number of iterations that different cameras carry out the tracking individually. We let \( \ell_i \) be the local estimation the camera has on the number of iterations gone since the last local association of a measurement to the target by at least one camera of the network, which is a global parameter that involves the whole network. This estimation is sent as part of the tracker message at every iteration. If the camera achieves the local data association of the tracker, the new value of this parameter is set to zero. Otherwise, the camera chooses as new value the minimum among all the values received, including its own, and adds one unit,

\[
\ell_i(k+1) = \left\{ \begin{array}{ll}
0 & \text{if target detected} \\
\min_{j \in C_i} (\ell_i(k), \ell_j(k)) + 1 & \text{otherwise}
\end{array} \right.
\]

The camera drops the target when \( \ell_i(k+1) \) is higher than a threshold \( \kappa \). The tracker ID is saved together with its gallery as old tracker to be recovered if the same target is back in the camera field of view or some other camera re-activates it. This process is checked during the local initialization. Before assigning a new ID, a re-identification score is computing between the new tracker gallery and the galleries from old trackers through Eq. (7) The re-initialization is accomplished if \( s_a \) is lower than \( \epsilon \).

D. Communication and bandwidth requirements.

The information shared between cameras at every iteration consists, for each active tracker, of the tracker ID, its predicted state, the measurements obtained in (2) and the counter of the last observation, \((ID_i, \bar{x}_i, u_i, U_i, \ell_i)\). This message is encoded using a total of 51 elements, representing less than 1kB of bandwidth information per tracker. In order to carry out the process explained in the Distributed Global Data Association, the message with the information related to the new trackers is sent together with appearance information. The appearance information exchange between cameras is composed by two appearance feature vectors required in the trackers initialization. Each one has 512 elements, representing 16,38kB of bandwidth information that is sent only once per tracker.

IV. EXPERIMENTS

A. Experimental setup.

Most of our experiments are run on data from the EPFL dataset [27]: Terrace set with 4 outdoor cameras, Laboratory, with 4 indoor cameras and Campus set with 3 outdoor cameras. A final experiment also uses a subset of the more recent Wildtrack dataset [28], composed of 7 views
from outdoor cameras. All the datasets have cameras with partially overlapped field of view. For the person detection, all experiments run the official Detectionen implementation [24], filtering the output with a process equivalent to non-maximal suppression.

Regarding evaluation, we use standard Multiple Object Tracking (MOT) metrics, including Multi Object Tracking Accuracy (MOTA) and Multiple Object Tracking Precision (MOTP), as defined in [29], and Identification Precision (IDP), Identification Recall (IDR) and their F1 Score (IDF1) as defined in [30]. In multi-object tracking settings, MOTA accounts for false positives, mismatches and misses, MOTP measures the ability of the tracker to estimate precise object positions, while IDP, IDR and IDF1 measure precision/recall information relative to the person identification.

All the evaluations follow the same process explained in [7], basically giving as a final result the median metric for all the cameras available in each dataset.

### B. Ablation Study and Topology effect

This first experiment analyzes three configurations of the proposed approach to evaluate the effects of the novel modules we propose to include. The simplest configuration is our implementation of the Distributed Kalman Filter using only geometric information in the data association process (DKF). A second version adds the appearance information from the local gallery (DKF + LDA). The latest version includes the distributed tracker management module in the system. This version represents the complete algorithm presented in the paper (DKF + LDA + DTM).

Besides the ablation study, this experiment analyzes the effects of different network topologies. For chain and ring topologies we have considered several network alternatives to make the evaluation independent of the individual quality of particular cameras in the tracking. The considered combinations are shown in Fig. 3.

![Fig. 3. Alternatives considered for (a) ring graph topologies and (b) chain graph topologies.](image)

Table I summarizes the results of all the tests in this experiment. In all of them, the configuration parameters from the proposed algorithm are set to $\alpha_{LDA} = 2000$, $\alpha_{GDA} = 50$, $\tau = 0.5$, $\kappa = 15$, $\epsilon = 0.25$ the gallery size to 20 samples with $N = 20$. The different parameters were defined in Sec. III-B,III-C.

Overall, we can see how both proposed modules (LDA and DTM) bring significant improvements across all metrics and datasets, with more positive influence in the identification metrics (IDF1, IDP and IDR) than the tracking metrics (MOTA, MOTP). For a few cases it would be slightly better to only apply DLA, but the penalization for including DTM in those few cases (decrease of less than 5%) is not nearly as significant as the benefits it brings in the rest of the cases (up to 20% increase in some connectivities with respect to the DKF+LDA configuration).

![Fig. 4 shows some qualitative results obtaining in this study for each of the tested datasets. The supplementary material provides additional results.](image)

### C. Comparison with other algorithms

This experiment compares the proposed approach (configured exactly as in the previous experiment) with recent centralized methods evaluated in [7]. They publish results

| Method               | Graph Connection | Results with **Terrace** | Results with **Laboratory** | Results with **Campus** |
|----------------------|------------------|--------------------------|-----------------------------|------------------------|

*Campus set with three cameras, consequently the results in complete graph and ring graph are the same.

Table I Variations of our proposed distributed system evaluated.
on public datasets running their proposed approach, Hierarchical Trajectory Composition (HTC), as well as two other baselines, Probabilistic Occupancy Map (POM) [31] and K-shorted Path (KSP) [27]. To make a fair comparison, the evaluation parameters are those described in [7]. Among the datasets used there that provide accurate camera-ground plane calibration (required to run our algorithm), for this study we picked the most challenging sequence of Terrace, where a high number of crossings and occlusions occur between targets. Note this does not intend to be a thorough evaluation, but rather an experiment to see where the proposed distributed approach gets in comparison with existing centralized approaches.

Previously discussed distributed approaches [9], [10] can not be included in this study because up to our knowledge they do not provide MOT metric results in available benchmarks, or focus on different goals and metrics as us. In [10], the experiments focused mainly on the consensus algorithm analysis whereas [9] uses its own camera network to test the proposed approach, showing as result the trajectories of the different individuals on the ground. Section II already highlighted our approach advantages with respect to these systems.

The results are summarized in Table II where we see better performance of our approach with respect to the centralized methods in two of the three graph topologies. The complete connection being the closest version to the centralized system gets an improvement of 9.11% in MOTA while the ring connection get better results by 4.14%. Finally the chain graph obtains lower but still comparable results to those of HTC algorithm. Regarding the bandwidth, for the centralized systems we compute it considering one hop communication of the images to a central server (4 frames of 288 × 360 RGB pixels). For the distributed system, we compute an upper bound of the bandwidth, considering that every iteration there are 9 active trackers, which is the maximum number of trackers active during the whole execution. Each tracker requires 0.78kB per frame, so when multiplied by the 4 cameras and the 9 trackers results 28.08kB. The total number of trackers in our algorithm is 24, that over all the iterations average a total of 0.15kB/frame. The sum of these two quantities result in the 28.23kB/frame of the Table.

![Fig. 4. Qualitative results. First row: Laboratory dataset. Second row: Terrace dataset. Third row: Campus dataset.](image)

### Table II

| Algorithm                  | MOTA | MOTP | Bandwidth [kB/frame] |

**D. Tracking in the Wild.**

This last experiment is a proof of concept focused on identifying and tracking a subset of 20 people in the WILDTRACK dataset [28]. This is a more challenging dataset than those considered in the previous experiments, including 7 cameras and strong light changes from different perspectives.

In order to carry out the re-identification process, it has been necessary to manually build a common gallery of each person to store in each camera (global gallery). We selected the 20 people that appear more frequently to compose this subset, and save an average of 6 patches per person trying to select one patch per point of view to form a global gallery intended to decide one of these 20 people needs to be tracked. For this experiment, we adapt the proposed algorithm to this new set up. The main changes are the use of the local and the global gallery joined in the data association process, and the management of cases 2) and 3) explained in III-C Distributed Global Data Association(DGA). In these cases, we execute the DGA being $a_i$ and $a_j$ the local galleries of the tackers. If the two trackers are from the same target, we merge their local galleries to compare them with the global gallery and reassign the ID. Since the calibration matrices only contemplate the transformation between the image plane and the main ground plane, the other areas of the image are ignored. For this experiment, because the scene conditions and the accuracy of the homographies are different, our algorithm is configured with $\alpha_{LDA} = 1000$, $\tau = 0.45$, $\kappa = 0.125$ and the gallery size is set to 5 with $N = 1$, reducing the space considered and assigning a more restrictive threshold to accept a match.

Figure 5 shows the images of the 7 cameras used in the tracking at one iteration illustrating the benefits and issues of the current version of the proposed algorithm. For example, cameras can correctly locate targets even if they are partially occluded or far away thanks to information shared from other cameras. This happens with camera 7 information about ID198, which helps camera 6 to identify it although it is occluded. It also allows camera 2 to identify the same target, even though it is too far away to be detected by the Detectron. In this dataset, the major problems are caused by the occlusions and crossing that generates mismatches between close and similar targets.

As explained, in this experiment we only consider a subset...
of 20 people from the dataset. Then, we concentrate the evaluation on the precision and recall on those 20 ID classes (IDF1, IDP and IDR). The unique change with respect to the evaluation in the EPFL dataset is the Intersection over Union (IoU) between the tracker and the ground truth to considered valid the predicted position. In this case, as the dataset is more challenge we define the threshold in 0.3. The results obtained for the complete and the ring connected graph are the following:

- Complete Graph. IDF1: 55.5 IDP: 44.6 IDR: 56.2
- Ring Graph. IDF1: 47.2 IDP: 44.1 IDR: 50.4

As we can see, the recall is higher than the precision in both cases. This tendency is probably caused by false positives in the re-identification, due to high similarity (specially in appearance) between people included and excluded from the tracked subset.

V. Conclusions

This paper has presented a new multi-target tracking approach for a distributed camera network, providing a global approach that deals with the distributed fusion of low and high level information. In this work, the challenges of the distributed systems have been addressed boosting the DKF with a fully automatic data association and a novel tracker manager to handle the misalignment of the high level information. The data association is based on geometric and appearance constraints. Furthermore, we add to the DKF a consensus maximizing the observability of the trackers in the whole network. The proposed approach is evaluated in challenging public benchmarks, reaching comparable results to centralized systems in high connectivity networks, and demonstrating the benefits with respect to a naive DKF implementation. The implementation of the DKF assumes synchronization of the cameras but the consensus-nature of the algorithm makes it amenable to a fully asynchronous through an event-triggered implementation. This and more sophisticated strategies of information selection to build the galleries are open challenges left for future work.
