ABSTRACT

Non-thermal hard X-ray and high-energy (HE; 1 MeV < E < 100 GeV) γ-ray emission in the direction of η Carina has been recently detected using the INTEGRAL, AGILE, and Fermi satellites. So far this emission has been interpreted in the framework of particle acceleration in the colliding wind region between the two massive stars. However, the existence of a very fast moving blast wave which originates in the historical 1843 “Great Eruption” provides an alternative particle acceleration site in this system. Here, we explore an alternate scenario and find that inverse Compton emission from electrons accelerated in the blast wave can naturally explain both the flux and spectral shape of the measured hard X-ray and HE γ-ray emission. This scenario is further supported by the lack of significant variability in the INTEGRAL and Fermi measured fluxes.

Keywords: acceleration of particles – radiation mechanisms: non-thermal – shock waves – stars: individual (Eta Carina)

1. INTRODUCTION

For a long time, η Carina—one of the most peculiar objects in the Milky Way—was believed to be a hypergiant luminous blue variable star. Recent observations, however, suggest that it is a binary system composed of a massive primary (M ★ ≳ 90 M⊙) and a less massive secondary (M ★ ≲ 30 M⊙; see, e.g., Hillier et al. 2001; Pittard & Corcoran 2002a, 2002b; Nielsen et al. 2007; Hinton & Aharonian 2007). η Carina experienced a historical outburst in the 19th century and ejected ∼12 M⊙ of gas which moves outward at an average speed of ∼650 km s−1 (Smith et al. 2003). This material formed the Homunculus Nebula which is expanding with a kinetic energy of ∼(4–10) × 1049 erg—roughly 10% of the energy released by a supernova explosion. The optical (Damineli 1996; Damineli et al. 2000) and IR (Whitelock et al. 1994, 2004) light curves suggest a binary period of 5.5 yr; moreover, the analysis of the X-ray light curves points to a highly eccentric orbit of e ∼ 0.9 (Corcoran et al. 2001; Okazaki et al. 2008). η Carina is a colliding wind binary (CWB) with powerful winds produced by both members of the system. The primary has a very high mass-loss rate of M1 ≳ 5 × 10−4 M⊙ yr−1 (Hillier et al. 2001; Parkin et al. 2009) and a terminal wind velocity of v1 ≳ (500–700) km s−1, whereas the secondary has a fast low-density wind with v2 ≳ 3000 km s−1 and M2 ≲ 1.0 × 10−5 M⊙ yr−1 (Pittard & Corcoran 2002a, 2002b). When supersonic expanding winds collide, they form a wind–wind interaction zone where charged particles can in principle be accelerated to high energies via the diffusive shock acceleration (DSA) process (see, e.g., Eichler & Usov 1993; Reimer et al. 2006). Observationally, particle acceleration in the wind-collision region of massive binary systems such as η Carina is suggested by the detection of non-thermal radio emission in several objects (see De Becker 2007 for a review). This indicates the existence of high-energy (HE; 1 MeV < E < 100 GeV) electrons in these systems.

There is also evidence for the presence of relativistic particles in η Carina with non-thermal X-ray emission recently reported by the INTEGRAL collaboration. The authors obtain an average luminosity of 7 × 1033 erg s−1 in the hard X-ray band (22–100 keV; Leyder et al. 2008). In the HE domain, a source spatially coincident with the η Carina position, and possibly variable, was reported by the AGILE collaboration (Tavani et al. 2009). A steady source in the same direction (including systematical and statistical errors; see Figure 1 and Table 1) was confirmed using the Large Area Telescope (LAT) on board the Fermi satellite (Abdo et al. 2009, 2010a). The luminosity in the HE domain between 100 MeV and 100 GeV as obtained from the energy flux given in Abdo et al. (2010a) for a source distance of 2.3 kpc is 1.6 × 1035 erg s−1, a factor of 20 higher than the INTEGRAL luminosity.

Given the large population of HE γ-ray sources detected by Fermi, with a significant fraction associated with pulsars, the chance probability of source confusion with a pulsar or another HE γ-ray source must be examined. Within a circle of 5° radius, 19 Australia Telescope National Facility (ATNF) pulsars with a spin-down luminosity E > 3 × 1033 erg s−1 (Manchester et al. 2005)—the sensitivity limit of the Fermi γ-ray pulsar catalog (Abdo et al. 2010b)—and 12 Fermi sources (Abdo et al. 2010a) have been detected. Thus, the probability of finding any of the HE γ-ray sources or ATNF pulsars within the Fermi error circle at the η Carina position is estimated to be less than 0.2%. Moreover, whereas pulsars typically have a cutoff in the energy spectrum ≲10 GeV, the spectrum of the Fermi source positionally coincident with η Carina shows significant flux above 20 GeV, making an association with a pulsar unlikely.

The light curves from all mentioned instruments, together with lower-energy X-ray data from RXTE, which probes the colliding wind region (CWR), are shown in Figure 2. Note that the flare reported by AGILE around phase p ≈ 0.96 was not confirmed using the more sensitive Fermi-LAT. Although INTEGRAL detected no significant hard X-ray emission during

3 Gomez et al. (2010) conclude from submillimeter observations that more than ∼40 M⊙ could have been ejected in the giant outburst. We restrict ourselves to the more conservative estimate of the kinetic energy in the expanding material.
periastron passage, the upper limit is consistent with steady emission. The absence of significant variability in the 50 keV and GeV regime as shown in Figure 2 is surprising in a CWB picture, especially during periastron passage where a collapse of the CWR is expected and hence no particle acceleration should occur.

The detections of hard X-ray and HE $\gamma$-ray emission in $\eta$ Carina have so far been interpreted in the framework of particle acceleration in the colliding winds of the two massive stars. However, the CWR of $\eta$ Carina is not the only place within the Fermi, AGILE, and INTEGRAL error circles, where particles can be accelerated via DSA to high energies. Recent observations show that $\eta$ Carina is surrounded at a distance of $\sim$0.25 pc by a very fast moving blast wave. The giant outburst of 1843 (also known as the “Great Eruption”) produced material which is now moving ahead of the Outer Ejecta, a ring-like structure of material that overruns the “Outer Ejecta,” a ring-like structure of material that mimics a blast wave moving into the interstellar medium (ISM) with velocities comparable to the historical supernovae RCW 86 (Vink et al. 2006) and SN 1006 (Vink 2005). Figure 1 shows the X-ray emission measured with Chandra and optical emission measured with the Hubble Space Telescope (HST). The positional uncertainty of the $\eta$ Carina position. In this work, the possibility of particle acceleration in the expanding blast wave of 1843’s Great Eruption is examined, and leptonic and hadronic origins of the observed $\gamma$-ray emission are investigated in detail.

2. PARTICLE ACCELERATION IN THE BLAST WAVE

SNRs start their evolution by a free-expansion phase of the ejecta and enter the pressure-driven Sedov phase, once the mass of displaced material roughly equals the ejecta mass. The transition between the two phases in the remnant surrounding $\eta$ Carina is expected to occur after 290 $(500)^{1/3} \text{yr}$ depending on the ambient density $n_H$, for a blast wave speed of 6000 $(3500) \text{km s}^{-1}$, respectively. The density of the medium surrounding the blast wave can be estimated by adopting two steady stellar winds which filled the volume around $\eta$ Carina prior to the Great Eruption. For typical wind speeds of 500 $\text{km s}^{-1}$ and a typical mass-loss rate of $(5–10) \times 10^{-4} \text{M}_\odot \text{yr}^{-1}$ (Hillier et al. 2001; Parkin et al. 2009), the density of the circumstellar medium would be on the order of 50 $\text{cm}^{-3}$ at a distance of 0.25 pc. Hence, the blast wave is currently in the transition between free-expansion and Sedov phases, implying that efficient particle acceleration is possible.

The distance of 0.25 pc of the blast wave from $\eta$ Carina used here is motivated by the conclusion of Smith (2008) that parts of the Outer Ejecta are currently being overrun by the blast wave and X-ray observations, whereas Seward et al. (2001) used a ring with the same radius to describe the soft X-ray shell coincident with the Outer Ejecta. On the other hand, for a steady shock speed of 3500 $\text{km s}^{-1}$ and an age of 167 yr, the expected distance of the blast wave to $\eta$ Carina is 0.6 pc. A wind solution of the fast-moving material, which would result in an increasing velocity with time, could explain such a difference. To account for the different distance estimates, the spectral energy distributions (SEDs) for both values are shown in Section 4.
Relativistic electrons and protons will gain energy when crossing the shock front of η Carina’s blast wave. In the limit of a strong shock, the particle crossing time $\Delta t$ is determined by the diffusion coefficient $\kappa$, expressed in terms of the Bohm diffusion coefficient:

$$\kappa = \eta \kappa_{\text{Bohm}} = 10^{23} \eta \text{ cm}^2 \text{s}^{-1} \left(\frac{E_{\text{GeV}}}{B_{\mu G}}\right); \quad (1)$$

the shock speed $v_s$, the particle energy $E_{\text{GeV}}$, and the magnetic field in the shock region $B_{\mu G}$ are expressed as

$$\Delta t = \frac{5 \eta \kappa_{\text{Bohm}}}{cv_s} = 1.75 \times 10^5 \text{s} \left(\frac{E_{\text{GeV}}}{v_s,10^8 \text{km s}^{-1} B_{\mu G}}\right). \quad (2)$$

The energy gain per shock crossing is given by $\Delta E/E = v_s/c$ and, hence, the acceleration timescale $\tau_{\text{acc}} = E/(\Delta E/\Delta t) \approx \eta \kappa/v_s^2$:

$$\tau_{\text{acc}} \approx 5 \times 10^7 \text{s} \eta v_s^{-2} \left(\frac{E_{\text{GeV}}}{B_{\mu G}}\right). \quad (3)$$

No magnetic field measurements are available in the region of the blast wave. However, for the Homunculus Nebula different estimates exist and are used in the following as a rough guide for the magnetic field strength in the region of interest. Aitken et al. (1995) derived magnetic field strengths of $O(\mu \text{G–mG})$ in the Homunculus Nebula, depending on the underlying process, from polarization measurements, which were based on dust grain alignment. However, the dust shell of the Homunculus appears to be neutral and is likely composed of silicates and Fe rather than typical ISM dust grains (Gail et al. 2005). Hence, for the purpose of this work, a lower magnetic field strength of $10 \mu \text{G}$ is assumed. In the Bohm limit and without energy losses, it would take about a year to accelerate an electron or proton to an energy of 100 GeV in a $10 \mu \text{G}$ field given a shock speed of 3500 km s$^{-1}$. This acceleration timescale is short compared to the time since the giant outburst (167 yr) and implies that charged particles can potentially be accelerated to TeV energies.

### 3. ORIGIN OF THE $\gamma$-RAY EMISSION

Protons and heavier nuclei accelerated in the expanding blast wave will interact with the ambient medium, producing $\pi^0$, decay $\gamma$-rays above $\sim 300 \text{ MeV}$. The timescale for inelastic proton–proton interactions is somewhat energy dependent but can be approximated as (Aharonian 2004)

$$\tau_{pp} = 3 \times 10^7 n_H^{-1} \text{yr}, \quad (4)$$

where $n_H$ is the density of hydrogen atoms cm$^{-3}$. From a veil of [O III] emitting material surrounding η Carina and its ejecta, Smith et al. (2005) estimate a mean density of 400 particles cm$^{-3}$ and Smith (2008) finds 500 particles cm$^{-3}$ in this region, implying $\tau_{pp} = (6–8) \times 10^4 \text{yr}$. This timescale is much longer than the age of the remnant and hence the $p-p$ channel is radiatively inefficient. To explain the observed level of $\gamma$-ray emission with this density of target material an energy of about $L_{\gamma} \epsilon_p \tau_{pp} \sim 3 \times 10^{48}$ erg in hadronic cosmic rays ($\epsilon_p \sim 0.1$ is the fraction of the proton energy released in $\gamma$-rays in a typical interaction) would be required. This is roughly 5% of the kinetic energy of the blast wave, quite plausible within the framework of DSA. However, it is hard to explain the Fermi emission below 300 MeV, and especially the INTEGRAL emission, in this scenario. Furthermore, the required maximum energy of protons as indicated by the curvature in the Fermi spectrum is well below the expected maximum acceleration energy associated with either the age or size of the system.

Contrary to hadronic cosmic rays, accelerated electrons will encounter significant energy losses during the acceleration process. They will predominantly lose energy via inverse Compton (IC) scattering on radiation fields present in the acceleration region, via synchrotron radiation in magnetic fields, and by bremsstrahlung in interactions with ambient material. The IC cooling time in the presence of a blackbody target radiation field with energy density $U_{\text{rad},eV \text{cm}^{-3}}$ for an electron of energy $E_{\text{GeV}}$ is (Moderski et al. 2005; Hinton & Hofmann 2009)

$$\tau_{\text{loss}} \approx 3.1 \times 10^8 \text{yr} U_{\text{rad},eV \text{cm}^{-3}}^{-1} E_{\text{GeV}}^{-1} f_{\text{KN}}. \quad (5)$$

Assuming that the radiation field of the whole Homunculus Nebula is concentrated on a point at 0.25 pc distance to the blast wave and follows a blackbody spectrum of 260 K temperature (Gehrz & Smith 1999), the energy density in IR photons which serve as target radiation field is $U_{\text{rad}} = 8 \times 10^3 \text{eV cm}^{-3}$, several orders of magnitude higher than the density of the cosmic microwave background $(0.27 \text{eV cm}^{-3})$ or typical ISM photon fields. For infrared target photons, the Klein–Nishina (KN) suppression of the IC cross section for electron energies $E \lesssim 100 \text{ GeV}$ is a less than 20% effect and is not considered in the following. The relevant IC cooling time for electrons in the blast wave region is therefore $\tau_{\text{loss}} \approx 4000 \text{yr} E_{\text{GeV}}^{-1}$. In a 10 $\mu \text{G}$ field, the synchrotron-loss timescale for 100 GeV electrons is of $O(10^6) \text{yr}$: IC losses will dominate unless $B > 2 \text{mG}$. In dense media, bremsstrahlung may also contribute significantly to the energy-loss rate of electrons. The estimated mean density of 400–500 particles cm$^{-3}$ implies a typical bremsstrahlung loss time of $\tau_{\text{brem}} \approx (8–11) \times 10^4 \text{yr}$. Therefore, at > GeV energies, IC emission is very likely to be the dominant emission process for electrons in this system.

The maximum electron energy is determined (for cooling-limited acceleration) by the balance between radiative energy losses and the rate of energy gain via DSA, when $\tau_{\text{loss}} = \tau_{\text{acc}}$:

$$E_{e,\text{max}} \approx 50 \text{GeV} v_s,10^8 \text{km s}^{-1} \sqrt{\frac{B_{\mu G}}{\eta}}. \quad (6)$$

This maximum energy for the measured blast wave speed is consistent with the HE $\gamma$-ray emission found by Fermi for moderate magnetic fields of 10 $\mu \text{G}$ and diffusion close to the Bohm limit. Moreover, the energy-loss timescale is much shorter than the age of the remnant, implying that the acceleration of electrons is indeed cooling limited in this system. In this scenario, most of the energy injected into the acceleration process emerges as IC radiation in the GeV domain. For such an efficient process the required energy input in electrons is modest: within an order of magnitude of $L_{\gamma,\text{sys}} \sim 10^{45} \text{erg}$. IC emission is expected to dominate over $p-p$ emission in this system as long as $E_e > 10^{-3} E_{\text{CR}}$.

Vannoni et al. (2009) performed numerical calculations where they studied acceleration and radiation of electrons in a radiation-dominated environment such as the one investigated in this work. Compared to the magnetic field of 10 $\mu \text{G}$ used here, the authors obtain, for magnetic fields of 100 $\mu \text{G}$ maximum, particle energies in the TeV regime, where KN effects become very significant.
Figure 3. Measured and calculated SED for the region within a few arcminutes of \( \eta \) Carina, showing the radio flux measured by Molonglo (Murphy et al. 2007) as an upper limit on the synchrotron flux, thermal X-ray emission as measured by MECS, which probes the wind–wind interaction region (Vioiti et al. 2002, 2004), the INTEGRAL measurement from Leyder et al. (2008), and the Fermi-LAT detection (Abdo et al. 2010a). The sensitivity of the H.E.S.S. instrument at TeV energies is shown for comparison. The curves show a single-zone time-dependent model for continuous injection of electrons over the 167 year history of the system and a maximum acceleration energy of 110 GeV. A radiation density of \( 8 \times 10^{34} \text{eV cm}^{-3} \), appropriate for a region at 0.25 pc from \( \eta \) Carina, is used for the solid curves, decreased to \( 1.4 \times 10^{34} \text{eV cm}^{-3} \), corresponding to 0.6 pc distance, for the dashed curves and increased to \( 2.2 \times 10^{34} \text{eV cm}^{-3} \), corresponding to 0.15 pc distance, for the dotted curves. A magnetic field strength of \( 10 \mu G \) is assumed. The bremsstrahlung component for each model is depicted in green.

(A color version of this figure is available in the online journal.)

4. SPECTRAL ENERGY DISTRIBUTION

Figure 3 shows the measured SED of the \( 1' \) region around \( \eta \) Carina together with calculated synchrotron and IC emission for the leptonic scenario outlined above (solid lines). The calculation is a single-zone time-dependent numerical model as described in Hinton & Aharonian (2007).

Electrons accelerated via the DSA process are expected to follow a power law in energy \( dN/dE_e \approx E_e^{-\Gamma_e} \), with index \( \Gamma_e \approx 2 \) and produce an IC (and synchrotron) \( \gamma \)-ray spectrum with spectral index \( \Gamma_{\gamma} = -((\Gamma_e + 1)/2) \). For continuous injection, IC cooling in the Thomson regime results in a spectral break with \( \Delta \Gamma_{\gamma} \approx 1/2 \). In the case of the Great Eruption 167 years ago, IC break energy is expected to lie at \( \approx 0.4 \text{ GeV} \) for a blast wave distance of 0.25 pc. As Figure 3 shows, for this distance the observed break between the INTEGRAL and Fermi spectra occurs somewhat below this energy, close to the expectation for the higher radiation field corresponding to a smaller distance of 0.15 pc. This value is broadly consistent with expectations since the relevant radiation field is the average value encountered over the history of the object. Furthermore, the system is far from radially symmetric and parts of the shell lie at significantly smaller than average distances to the Homunculus. The Fermi data indicate a HE cutoff at an electron energy of \( \approx 100 \text{ GeV} \), very close to the expected cutoff for IC-cooling-limited acceleration.

The dashed and dotted lines in Figure 3 demonstrate the effect of adjusting the main parameter of the model. For the dashed curves the radiation field is decreased to that expected at 0.6 pc (rather than 0.25 pc) from \( \eta \) Carina. In this case, an increase in energy in electrons by a factor of 2.3 would be required to match the Fermi flux. For the dotted curves the radiation field is increased to that expected at 0.15 pc from \( \eta \) Carina. All curves were produced assuming a magnetic field of 10 \( \mu G \). Magnetic fields higher than \( \approx 20 \mu G \) are excluded in this scenario by the limit on non-thermal radio emission from Molonglo. For a blast wave distance of 0.6 pc, the shape of the resulting model spectrum reproduces the data in the HE domain less well. A model with a realistic time- and space-dependent radiation field would be expected to fall in the region defined by the three curves shown.

5. SUMMARY

It appears that the properties of the HE non-thermal emission of \( \eta \) Carina are consistent with an origin at the high-velocity blast wave of the Great Eruption of 1843. As Figure 3 demonstrates, the position of the spectral break between the Fermi and INTEGRAL domains, and the cutoff energy measured using Fermi, can be explained as a cooling break and an acceleration limit, respectively.

A prediction of this model is an extended emission region and hence non-variability of the signal. The non-variability of the source in the \( \gamma \)-ray regime is supported by the Fermi observations. While Fermi and INTEGRAL do not provide sufficient angular resolution to resolve the blast wave (see Figure 1), high-resolution radio observations will be able to resolve non-thermal radio emission from this acceleration site. Detection of a radio shell at the location of the shock would support the proposed scenario.

The time elapsed since the ejection of the very fast material by \( \eta \) Carina is comparable to the age of the youngest Galactic SNR G 1.9+0.3 and between the ages of the remnants of SN 1987A and Cas A. It may provide important insights into particle acceleration and production of non-thermal radiation during the early stages of remnant evolution where only very few objects can be studied.

We thank the anonymous referee for very helpful and informative comments which improved the quality of the Letter. We also thank Felix Aharonian, Werner Hofmann, and Olaf Reimer for their input and suggestions. Furthermore, the support of the authors’ host institutions and additional support from the German Ministry of Education and Research (BMBF) are acknowledged.
