Pre-synaptic Muscarinic Excitation Enhances the Discrimination of Looming Stimuli in a Collision-Detection Neuron

Highlights

- Calcium fluorescence closely tracks dendritic membrane potential for looming stimuli
- Local muscarinic receptors between presynaptic LGMD afferents mediate excitation
- Muscarinic receptors help distinguish coherent from incoherent expanding objects
- Global inhibition normalizes the excitatory synaptic input to the LGMD during looming

In Brief

In the locust visual system, Zhu et al. study the presynaptic circuitry of a collision-detecting neuron. They characterize local excitatory connections mediated by muscarinic acetylcholine receptors tuning the neuron to coherently expanding visual stimuli. Additionally, they describe a global inhibitory mechanism normalizing the excitatory inputs the cell receives.

SUMMARY

Visual neurons that track objects on a collision course are often finely tuned to their target stimuli because this is critical for survival. The presynaptic neural networks converging on these neurons and their role in tuning them remain poorly understood. We took advantage of well-known characteristics of one such neuron in the grasshopper visual system to investigate the properties of its presynaptic input network. We find the structure more complex than hitherto realized. In addition to dynamic lateral inhibition used to filter out background motion, presynaptic circuits include normalizing inhibition and excitatory interactions mediated by muscarinic acetylcholine receptors. These interactions preferentially boost responses to coherently expanding visual stimuli generated by colliding objects, as opposed to spatially incoherent controls, helping to discriminate between them. Hence, in addition to active dendritic conductances within collision-detecting neurons, multiple layers of inhibitory and excitatory presynaptic connections are needed to finely tune neural circuits for collision detection.

INTRODUCTION

Both in vertebrates and invertebrates, collision-detecting neurons are typically located in higher-order nuclei and neuropils, several synapses away from the periphery. In fish, e.g., collision-detecting neurons are found in the optic tectum and the hindbrain (Preuss et al., 2006; Dunn et al., 2016; Temizer et al., 2015). In birds, they were identified in the nucleus rotundus of the thalamus (Sun and Frost, 1998). In mice and cats, they have been documented in the superior colliculus (Liu et al., 2011; de Vries and Clandinin, 2012; Oliva and Tomsic, 2014) and in the brain (Zhao et al., 2015). In insects and crustaceans, collision-detecting neurons are found in the lobula complex of the optic lobes (de Vries and Clandinin, 2012; Wu et al., 2016; Gabbiani et al., 2002; Oliva and Tomsic, 2014) and in the brain (von Reyn et al., 2014; Rind and Simmons, 1992). This leaves room for presynaptic networks to implement, through specific connectivity patterns, the neural computations required to shape their responses.

The lobula giant movement detector (LGMD) is an identified visual neuron in the third neuropil of the optic lobe of orthopteran insects such as locusts (O’Shea and Williams, 1974). It responds preferentially to objects approaching on a collision course or their two-dimensional simulations on a screen (i.e., looming stimuli; Hatsopoulos et al., 1995; Rind and Simmons, 1992) and plays a role in visually evoked escape behavior (Fotowat and Gabbiani, 2011; Santer et al., 2006). The LGMD is exquisitely tuned to looming stimuli (e.g., Judge and Rind, 1997; Gray et al., 2001; Gabbiani et al., 2001), due in part to active conductances close to its spike initiation zone and within its dendritic tree (Peron and Gabbiani, 2009; Dewell and Gabbiani, 2018). A host of neurons with response characteristics resembling those of the LGMD (Gabbiani et al., 1999) have been described (Sun and Frost, 1998; Liu et al., 2011; de Vries and Clandinin, 2012; Oliva and Tomsic, 2014; Temizer et al., 2015; Dunn et al., 2016; von Reyn et al., 2017). In none of these systems do we understand how spatio-temporal interactions within presynaptic circuits shape their responses.

The LGMD receives onto its excitatory dendritic field a retinotopic projection from an entire visual hemifield originating from ommatidia (facets) on the eye (Zhu and Gabbiani, 2016). Electron microscopy revealed that the transmedullary afferents (TmAs) building it make reciprocal synapses on their neighbors at their presynaptic terminals on the LGMD (Rind and Simmons, 1998). Histology and immunocytochemistry demonstrated that these local lateral connections are cholinergic and not GABAergic. They might thus mediate inhibition through muscarinic acetylcholine receptors (mAChRs; Rind and Simmons, 1998; Rind and Leitinger, 2000). However, muscarinic acetylcholine receptors can be excitatory (Brown, 2010). If lateral connections are inhibitory, then the activation of one afferent would inhibit adjacent ones, setting up a race between excitation and inhibition that might lead to specific responses for expanding over translating stimuli (Rind et al., 2016). By contrast, if the connections are excitatory, then the activation of one afferent would increase synaptic release from adjacent ones, enabling stronger and longer-lasting responses to coherently expanding stimuli, such as objects approaching on a collision course.

Calcium enters the LGMD excitatory dendritic field exclusively through the nicotinic receptors associated with its TmAs (Peron...
et al., 2009). Thus, calcium imaging accurately monitors activation of the afferents and their lateral interactions. To investigate whether lateral interactions between TmAs are excitatory or inhibitory, we locally applied the muscarinic acetylcholine receptor antagonist scopolamine or the agonist muscarine and tested responses to visual stimuli. In all cases, the lateral interactions proved to be excitatory. This raises a conundrum: because lateral connections amplify an excitatory input that grows rapidly during object approach, how is it maintained within the dynamic range of the LGMD? One possibility is for the presynaptic network to rely on global, normalizing inhibition, a feature present in many sensory circuits (Carandini and Heeger, 2011). Our evidence suggests that such inhibition is indeed present among presynaptic LGMD excitatory afferents. What role does lateral excitation play in collision detection? We show that it helps the LGMD discriminate solid objects approaching on a collision course from spatially incoherent matched controls, a computation critical to elicit appropriate escape behaviors (Dewell and Gabbiani, 2018).

RESULTS

Looming Stimuli Evoke an Orderly Activation of the LGMD Excitatory Dendritic Field

We started by mapping the activation pattern elicited by different regions of the visual display on the LGMD’s excitatory dendritic field (Experimental Procedures). We flashed squares at 5 locations on the display, 3 colors represent flashes with different distances from the display center, b: a looming stimulus was then presented. It expanded from the center square and eventually covered locations where the other flashes were presented. c: LGMD excitatory dendritic field. Dendritic branches activated by the 5 flashes are shown in red, green, and blue.

(B) The black dashed line indicates the start of the stimulus. a: angular size time course ($\psi/v = 120$ ms). Stimulus parameters were as follows: radius $l$, speed $v$, and angular size $2\psi$ (schematics). b: average relative fluorescence change at the center branch (red) and two sets of branches symmetrically surrounding it (green and blue) in one animal. Time is relative to maximal stimulus size (80 ms before projected collision). c: mean (solid lines) and SD (shaded areas, $n = 5$; $n$, number of animals) of average $dF/F$ (normalized to maximum $dF/F$ in response to center square flash for each animal) at the center branch (red) and at two surrounding branch sets (green and blue). b and c: red, green, and blue rectangles (arrowheads) represent the time during which the stimulus edges moved across locations activated by red, green, and blue flashes. Over the white intermediate regions, the stimulus edge would be within the receptive fields of branches on either side.

(C) The same as (B) but enlarged. The black dashed line indicates the time when the stimulus reached its maximum size; the dashed blue line represents the projected collision time. The red double arrow indicates the time interval during which the stimulus edge activates both the red and green branches (A, c) because of overlapped activation (Zhu and Gabbiani, 2016).

(D) a: LGMD excitatory dendritic field with 10 selected dendritic branches indicated in colors. b: time course of average $dF/F$ at each selected branch of a. The horizontal black dashed line is threshold for branch activation.

(E) a: the y axis represents the time when the rising phase of each trace in (D), b, crosses the threshold. The branch with the earliest rise time at threshold is the looming center. The x axis represents the distance in the imaging plane from each dendritic branch to the looming center. The colors match those in (D). b: the same as a across 5 animals. All dendritic branches are plotted in the same color for each animal.

(F) a: time-integrated $dF/F$ for each dendritic branch in (D) as a function of distance from the looming center. b: the same as a across 5 animals. Data from each animal are plotted in a different color.

See also Figure S1.
separated the stimuli by $8^\circ$ to minimize overlap. We found that the branches activated by these stimuli intersected minimally (Figure 1Ac). How does a looming stimulus activate such a retinotopic mapping? To address this question, we presented looming stimuli with a high half-size ($h$) to speed ($l/v)$ ratio and, thus, a long time of approach (Fotowat and Gabbiani, 2007), maximizing our ability to resolve temporally the associated calcium signals (Figure 1Ba; Video S1). These stimuli expanded symmetrically from the center of square 3 (Figure 1Ab). Figures 1Bb and 1Cb show the average dendritic calcium responses to these stimuli at the center branches and two sets of branches symmetrically surrounding them. Unexpectedly, given the retinotopic organization, we found that the relative fluorescence change, dF/F, of the center branches reached its peak after the edge of the looming stimulus had moved outside of the square to which they mapped. The calcium signal continued to increase even after the edges of the stimulus had expanded beyond the 4 lateral squares. The central branches also activated earlier and reached a higher peak dF/F. These results were consistent across animals (Figures 1B and 1Cc). Finally, the dF/F peak times of the center and the two sets of surrounding branches were staggered in time (Figure S1B), a feature better resolved in the next set of experiments (Figure 2J).

We analyzed the calcium responses on a finer spatial scale by considering each imaged dendritic branch (Figure 1Da). We defined a threshold activation as 5 times the dF/F baseline noise (Figure 1Db; Experimental Procedures). We call the time at which dF/F crosses this threshold relative to that at which the stimulus reaches its maximal size the rise time. We found that the branch that had the earliest rise time mapped to the center square on the display (Figures 1D and 1Ea; cf. Figure 1Ac). We call this branch the “looming center.” As predicted from retinotopy, the rise time increased with branch distance from the looming center (Figure 1Eb). dF/F integrated over time up to its peak, a measure of cumulative calcium influx, decreased as a branch lay farther from the looming center (Figure 1F). Thus, looming stimuli generate an orderly activation of dendrites that lasts over the entire stimulus and decreases in strength.

**Calcium Responses at the Looming Center Track Subthreshold Membrane Potential**

dF/F changes are slower than membrane potential ($V_m$) changes because of buffering and the binding kinetics of calcium dyes. We compared the dF/F to looming stimuli obtained using either Oregon green 1,2-Bis(2-Aminophenoxyl)ethane-N,N,N',N'-tetraacetic acid (BAPTA)-1 (OGB-1) or Oregon green BAPTA-5N (OGB-5N) and found OGB-5N to have faster kinetics (Figures S2A and S2B). We checked how closely OGB-5N calcium responses track the subthreshold membrane potential by simultaneous recordings. The calcium signals from individual dendritic branches (Figure 2A) are plotted with the median filtered $V_m$ in Figures 2B and 2C. The dF/F at the looming center best matched the subthreshold $V_m$. This was also true at faster approach speeds (Figures S2C–S2F). The match was close over the rising phase of $V_m$ up to its peak, when synaptic excitation generating the calcium influx dominates, but not over $V_m$’s decaying phase, when synaptic inhibition dominates (Gabbiani et al., 2002, 2005). We computed the cross-correlation ($xcorr$) between $V_m$ and dF/F during the rising phase of $V_m$ as a function of time lag (Figures 2D and 2E). We found a high peak cross-correlation that increased as the peak dF/F increased and eventually saturated (Figures 2F and 2G). The peak of the cross-correlation decreased with distance from the looming center (Figures 2H and 2I). To resolve the spread of peak activation times across dendritic branches (cf. Figure S1B), we plotted the time lag at peak cross-correlation as a function of branch distance to the looming center (Figure 2J). The minimum lag was at the looming center, 0.11 ± 0.08 s. As expected from these results, the peak of the cross-correlation decreased with increasing peak time lag (Figure 2K). To summarize, the calcium signal at the looming center closely tracked the membrane potential with a delay of 110 ms; other branches experience nearly identical activation that is increasingly delayed with distance from the looming center.

**Muscarine Increases and Scopolamine Decreases Excitatory Dendritic Activation to Looming Stimuli**

To study putative muscarinic acetylcholine receptors at the presynaptic terminals of the LGMD, we compared dendritic activation with looming before and after locally puffing muscarine in the lobula (Experimental Procedures). The activated dendritic area increased after puffing muscarine (Figure 3A). Calcium influx also increased close to the spike initiation zone (SIZ; Figure 3A), where voltage-gated calcium channels are activated by LGMD spiking (Peron and Gabbiani, 2009). Muscarine increased dF/F across dendritic branches (Figures 3B–3E). To quantify the increase in activated area, we computed its two principal axes relative to its center of mass and projected the dF/F along each of them (Figures S3A–S3E). The first and second principal axes approximately aligned with the ventral-dorsal and lateral-medial axes of the dendritic tree, allowing us to assess the change in dF/F relative to the axes of retinotopy and of looming stimulus expansion (elevation and azimuth in visual space; Zhu and Gabbiani, 2016). We computed the full width at half maximum (FWHM) of the activated area along the principal axes before and after drug application (Figure S3F). These curves broadened following muscarine application (Figure 3F). The peak dF/F decreased with increasing distance from the looming center before and after puffing muscarine (Figure 3G). The magnitude of the slope of the peak dF/F as a function of the distance from the looming center decreased after puffing muscarine. However, we did not find a difference between the rise time at threshold before and after puffing muscarine (Figure 3H). We also applied muscarine locally in the absence of visual stimuli and quantified the dF/F across dendritic segments (Figure S3G). Figures S3H and S3I depict such spontaneous dF/F traces before and after muscarine application. The increase in dF/F held across animals (Figure S3J).

We then compared activation on the excitatory dendritic field to looming stimuli before and after puffing scopolamine (Figures 3I–3P). Activation strongly decreased (Figure 3I), as did dF/F close to the SIZ (Figure 3I, arrowhead). On selected dendritic branches (Figure 3J), we found a uniform dF/F decrease (Figure 3K versus 3L). This result was consistent across animals (Figure 3M), although the change in the activation area was not significant after pooling across animals (Figure 3N, legend). The peak dF/F also decreased with increasing distance from the looming
center after puffing scopolamine (Figure 3O). However, we did not observe a notable difference in the slope of the peak dF/F as a function of distance from the looming center before and after puffing scopolamine (Figure 3O). The rise time at threshold after puffing scopolamine was later than that before puffing (Figure 3P). Thus, the effects of scopolamine are qualitatively opposite to those of muscarine, in spite of quantitative differences.

Finally, we tested the effect of scopolamine on LGMD spiking by recording its activity to small transient stimuli flashed across the visual field (Figures S3K–S3M). Scopolamine decreased spiking by ~50%, suggesting that muscarinic acetylcholine receptors are tonically active because the flashes likely activated one or two ommatidia.

Scopolamine and Muscarine Do Not Affect Presynaptic Dynamic Lateral Inhibition
The LGMD’s response to a small translating object is inhibited by wide-field drifting stripes flanking it, provided they are sufficiently close (O’Shea and Rowell, 1975). This dynamic lateral (DL) inhibition protects the LGMD from habituation caused by background
Figure 3. Effect of Muscarine and Scopolamine on Looming Responses

(A) a: LGMD activation to looming, shown as peak dF/F at each activated pixel (color scale, right; average over 3 trials in 1 animal). Blue and yellow dashed arrows indicate the first and second principal axes. b: the same after puffing muscarine (average over 3 trials).

(B) LGMD excitatory dendritic field with selected dendritic branches indicated by different colors.

(C) a: stimulus angular size time course (t = 120 ms). b: average dF/F in response to this stimulus at each selected dendritic branch (B) in one animal.

(D) The same as (C) after puffing muscarine.

(E) Peak amplitude of dF/F on each dendritic branch after versus before muscarine (p = 4.84 × 10⁻³⁰, paired t test).

(F) a: projection of peak dF/F onto the first principal axis as a function of distance along the axis after normalizing to peak value without (blue) and with muscarine (red). Red and blue shadings, SD. FWHM before muscarine, 148.7 ± 13.3 µm (mean ± SD); after: 252.2 ± 13.2 µm (p = 0.0002, paired t test, before versus after). b: the same analysis but along the second principal axis. FWHM before muscarine: 61.2 ± 15.7 µm; after: 90.6 ± 18.2 µm (p = 0.0016).

(G) Peak amplitude of dF/F on each dendritic branch as a function of branch distance to the looming center before (control) and after puffing muscarine (n = 5). Corresponding lines are linear regressions. Line slopes are significantly different (38 data points, p = 0.023, ANCOVA).

(H) Rise time at threshold (as in Figure 1D) after versus before puffing muscarine (p = 0.31, paired t test).

(I) a: LGMD activation to looming, shown as peak dF/F at each activated pixel (color scale, right; average over 3 trials in 1 animal). b: the same after puffing scopolamine (average over 3 trials).

(J) LGMD excitatory dendritic field with selected dendritic branches indicated by different colors.

(K) a: stimulus angular size time course (t = 120 ms). b: average dF/F at selected dendritic branches, with colors matched to (J).
motion (e.g., during locomotion) and suppresses excitation early during looming (Gabbiani et al., 2002; Rind et al., 2016). The anatomical location of DL inhibition remains unknown. Because muscarinic acetylcholine receptors presynaptic to the LGMD are excitatory, they are unlikely to implement it. Because DL inhibition was predicted to be mediated by muscarinic acetylcholine receptors in presynaptic terminals to the LGMD (Rind and Simmons, 1998), we designed visual stimuli to probe this possibility. The baseline condition consisted of a small translating black square that appeared at one edge of the screen and later moved until completely outside of the display (Figure 4A; Video S2). This allowed us to separate the LGMD’s responses to the square’s appearance and its motion. Under the test conditions, the same stimulus moved, flanked by two gratings drifting in the same direction (Figure 4B). The distance between the two gratings was varied from 7.5° to 70°, yielding maximal and minimal activation of DL inhibition, respectively.

In response to the small translating stimulus, the dendritic area activated under control conditions was larger than that activated by looming stimuli (compare Figure 4Ca, with Figures 3A and 3I). This is surprising because looming stimuli elicit stronger LGMD firing than translating stimuli (Peron and Gabbiani, 2009). After puffing scopolamine, dendritic activation decreased (Figure 4Cb). On each selected dendritic branch (Figure 4D), dF/F in response to a translating stimulus was stronger than in response to the same stimulus flanked by drifting gratings (Figures 4E and 4F). Under test conditions, the amplitude of the dF/F decreased, but DL inhibition persisted (Figures 4G and 4H). We employed flanking gratings with 4 separations and found the peak dF/F to be smaller after than before puffing (Figure 4I; p < 10−4 for all stimuli, paired t test). The time at peak dF/F before and after puffing did not change for two separations and only slightly in the other 3 cases (median change: −1.1% at 70°, −4.2% at 7.5°, −1.8% for no grating, Figure 4J). The mean peak dF/F decreased with closer flanking gratings both before and after puffing (Figure 4K). However, the difference in mean peak dF/F showed no difference (Figure 4L, legend). This suggests that blocking muscarinic acetylcholine receptors presynaptic to the LGMD did not influence DL inhibition.

We tested the influence of muscarine on DL inhibition using the same protocol and found no effect (Figure S4). Thus, muscarinic acetylcholine receptors presynaptic to the LGMD do not appear to generate DL inhibition.

**Horizontal Band-Restricted Looming Stimuli Activate Lateral Branches Better Than Looming Stimuli**

To study dendritic activation elicited by stimulus expansion along the cardinal axes, we designed looming stimuli restricted to horizontal (along the dorsal–ventral eye axis because of the 90° head rotation performed during the dissection; Experimental Procedures) or vertical (anterior–posterior axis) bands (Figure 5A). Because of the retinotopic mapping, the dF/F associated with horizontal band-restricted (HBR) stimuli mapped approximately onto the first principal axis of the response to a standard looming (SL) stimulus (Figure 5Ab, left). The vertical band-restricted (VBR) stimuli resulted in increased dF/F along the second principal axis. We found that the activation width of the HBR response was wider than that of the SL response along the first principal axis (Figure 5Ab), in spite of the higher peak dF/F for the latter stimulus. The activation width of the VBR response was narrower than that of the SL response, as expected. The peak dF/F decreased with distance from the looming center for the SL and VBR stimuli but not for the HBR one (Figure 5B). We compared dF/F along the first principal axis for the 3 stimuli and found that the HBR stimuli yielded the wider curve, followed by the SL and VBR stimuli (Figure 5Ca). Peak activation was not at the looming center for the HBR stimuli. Along the second principal axis, the width of activation was reversed, as expected, with the VBR stimuli yielding a slightly broader curve than SL and HBR stimuli (Figure 5Cb). The FWHM of the response to HBR stimuli was larger than that for the SL stimulus, whereas that of the VBR stimuli was smaller (Figure 5Db). The situation was reversed along the second principal axis. After applying muscarine, responses to all stimuli increased. Additionally, the differences between HBR and SL stimuli along the first principal axis were abolished, as were those of VBR and SL stimuli along the second principal axis (Figure 5S). Motivated by the wide activation for HBR stimuli, we compared the activation elicited by small squares translating horizontally with that of looming stimuli. We again observed a broader activation for the translating squares along the first principal axis but not along the second one (Figure S6). The following set of experiments directly addresses the origin of the unexpectedly broad dendritic activation observed for spatially restricted stimuli.

**Presynaptic Muscarinic Acetylcholine Receptors Partially Counteract Global Inhibition Upstream of the LGMD**

To understand why the activation of lateral branches is weaker in response to SL than to HBR stimuli and to small translating squares, we designed flicker-off stimuli with different angular sizes (Figure 6A). The activated dendritic area initially increased with stimulus size (Figure 6B). However, for sizes >40°, the peak dF/F decreased as angular size further increased (Figure 6B). This suggests the existence of size-dependent inhibition upstream of the LGMD excitatory dendrites. We tested the
Figure 4. Test of the Influence of Scopolamine on Lateral Inhibition

(A) a: stimulus schematics (control). b: stimulation time course. Time 0–t<sub>a</sub>, bright display; t<sub>a</sub>, stimulus on at right display edge; t<sub>a</sub>–t<sub>b</sub>, stimulus stays still; t<sub>b</sub>–t<sub>c</sub>, stimulus translates from right to left until it moves out of display.

(B) a: stimulus schematics (lateral inhibition); flanking gratings temporal frequency, 6 luminance transitions per second, 14°/s. Grating width, 25°. sep., separation. b: stimulation time course. Time 0–t<sub>a</sub>, bright display; t<sub>a</sub>, stimulus on at right display edge, gratings on; t<sub>a</sub>–t<sub>b</sub>, stimulus stays still; t<sub>b</sub>–t<sub>c</sub>, gratings drift; t<sub>b</sub>+0.2 s–t<sub>c</sub>, stimulus translates from right to left until it moves out of display; t<sub>c</sub>, gratings stop drifting.

(C) a: dendritic activation to translating stimulus. b: dendritic activation to the same stimulus after puffing scopolamine.

(D) LGMD excitatory dendritic field with selected dendritic branches indicated by different colors.

(E) a: average dF/F time course (over 3 trials) at each dendritic branch in (D) to the stimulus as in (A). Vertical dashed lines: black, time when stimulus appears; red, time when stimulus starts translating; blue, time when stimulus moves out of display. The asterisk and plus markers on each curve indicate calcium baseline and peak dF/F to the translating stimulus, respectively. b: dF/F amplitude computed by subtracting baseline (asterisks) from peak dF/F (plus symbols) for each curve in a (matched color) and plotted as a function of peak dF/F time.
In (I)–(L), n = 5. Drifting gratings. No significant statistical difference of means was found between any two groups (p = 0.66 one-way ANOVA).

Outside of this range (outliers) are plotted individually as crosses. Purple dots: translating stimuli, no drifting gratings. Green, light green, red, and blue dots: translating stimuli and lateral drifting gratings separated by 70 µm. In (H) the same as (F) after puffing scopolamine. In (G) the same as (E) after puffing scopolamine.

Peak dF/F of the center branch (Figure 6C) and the mean peak dF/F of all selected branches (Figure 6D) decreased as the size of the stimulus exceeded 40°. After puffing scopolamine, the mean peak dF/F was reduced for stimuli of a size <60° (Figure 6E). The peak dF/F of the center branch (Figure 6E) and the mean peak dF/F of all branches (Figure 6F) increased as stimulus size increased from 10° to 40°, but it exhibited no decrease as stimulus size increased to 100°. This suggests that muscarinic acetylcholine receptors partially counteract global inhibition upstream of the LGMD.

**Blocking Muscarinic Lateral Excitation Decreases the LGMD’s Spatial Coherence Preference**

The LGMD is selective for the spatial coherence of approaching objects. This selectivity is partially explained by the interaction of scopolamine and muscarine on this global inhibition.

**Figure 5. Calcium Responses to Looming Stimuli Restricted to Horizontal and Vertical Bands**

(A) a: from left to right, schematics of looming stimulus, HBR, and VBR looming stimuli, respectively. b: from left to right, LGMD dendritic field activation to the same stimuli. Red and blue arrows on left indicate the first and second principal axis, respectively.

(B) a: 8 selected regions of interest (ROIs) represented by different colors in an example LGMD. The white arrow points to the looming center. The red arrow indicates the first principal axis of the looming response. b: peak dF/F in the 8 ROIs to SL (black crosses), HBR (red dots), and VBR (blue circles) stimuli. Solid lines indicate linear regressions (n = 5; **p < 0.01; n.s., not significant [i.e., p > 0.05], paired t test, ANCOVA test of slopes).

(C) Projection of peak dF/F onto the first (a) and second (b) principal axes as a function of distance along the axis after normalizing to peak value in response to SL (black), HBR (red), and VBR (blue) stimuli, respectively. Red, black, and blue shadings, SD (n = 10).

(D) Boxplots of the full width at half-maximum (FWHM) of the curves in (C) along the first (a) and second principal axis (b) to the SL or the HBR/VBR stimuli (n = 10, *p < 0.05, **p < 0.01, paired t test). Box plotting conventions are described in the legend to Figure 4K.

See also Figures S5 and S6.
of hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels with a slowly inactivating K⁺ current in the dendrites of the LGMD (Dewell and Gabbiani, 2018). Because presynaptic lateral excitation is likely local (Rind et al., 2016; Zhu and Gabbiani, 2016), we reasoned that it might increase responses to coherently expanding objects. To test this, we designed stimuli with varying degrees of coherence by dividing the screen in an array of 2° wide “coarse pixels” roughly spanning the receptive field of a single ommatidium. We replaced the dark edge motion associated with a looming stimulus expanding across each coarse pixel by an equivalent uniform decrease in luminance. The resulting stimulus, which we call a “coarse loom” (Figure 7A), elicits LGMD responses nearly identical to those of SL stimuli (Jones and Gabbiani, 2010; Dewell and Gabbiani, 2018). Stimuli with decreasing coherence can be generated from coarse looms by randomly displacing individual coarse pixels increasingly far from their original position (Figure 7A). Retinotopy implies that, as stimulus coherence increases, synaptic activation in the LGMD dendrites becomes more local.

We presented such stimuli while recording the firing rate of the LGMD before and after blocking it with scopolamine. The timing of LGMD firing remained similar after adding scopolamine, but with much lower firing rates (Figures 7B and 7C). Responses to SL stimuli decreased from 58 ± 16 to 17 ± 7 spikes after addition of scopolamine (mean ± SD, p = 0.004, paired t test). Responses to incoherent stimuli were reduced as well (Figure 7C), from 30 ± 8 to 11 ± 6 spikes (p = 0.017). For every animal, there was a decrease in LGMD firing (p ≤ 0.004, analysis of covariance [ANCOVA]) and a reduced coherence-dependent increase in firing (Figure 7D). Coherence preference decreased from 0.28 to 0.07 spikes per percent coherence (Figure 7E). Because scopolamine reduced responses at all coherence levels, we calculated the coherence-specific reduction by subtracting from the reduction in coherent looming response the reduction in incoherent response and by expressing it as a percentage of the control looming response. We found a 37.1% ± 17.8% (mean ± SD) specific reduction for responses to coherent looming stimuli (p = 0.01, paired t test). These results indicate that lateral excitation shapes the LGMD’s preference for coherently expanding stimuli. Additionally, they suggest that lateral excitation is implemented locally because the effects of scopolamine increase with coherence and, thus, as synaptic activation of the LGMD dendrites becomes increasingly local.

In summary, our results and earlier anatomical ones (Rind et al., 2016) suggest that feedforward excitation impinging on the LGMD (Figure 7F) is differently organized than what was
Figure 7. Scopolamine Reduced Coherence Preference and Schematic Models of Candidate Neural Circuits Presynaptic to Dendritic Field A of the LGMD

(A) Illustration of coherent and incoherent stimuli. For coarse looms, grayscale levels are set so that the luminance in each coarse pixel is equal to that of standard looms in every frame. For reduced coherence looms, the spatial locations of coarse pixels were altered (Experimental Procedures).

(B) LGMD’s response to looming stimuli ($l/v = 50$ ms) decreased after addition of scopolamine. The lines and shaded region indicate mean and ± 1 SD.

(C) LGMD’s response to a spatially randomized stimulus also decreased after addition of scopolamine. Plotting conventions are as in (B).

(D) LGMD responses increase with stimulus coherence (Pearson $r = 0.90$, $p = 0.006$), but this coherence preference decreased after scopolamine ($p = 0.008$, ANCOVA test of slopes). Thin lines indicate data from individual animals. Thick lines and points represent population average. Error bars indicate ± 1 mad.

(E) Scopolamine caused a decrease in coherence preference (calculated from the slopes of the lines in C; $p = 0.022$, paired t test). There is an average decrease from 0.28 spikes to 0.07 spikes per percent coherence. Gray lines connect individual data points, and dots and whiskers indicate mean ± 1 SD.

(F) Overview of the pathways impinging on the LGMD. Feedforward inhibition impinging on two other dendritic fields was not studied here. For feedforward excitation onto the excitatory dendritic field, colored dots illustrate retinotopy. Ph, photoreceptors; LMC, lamina large monopolar cells; TmA, transmedullary afferents.

(legend continued on next page)
assumed up to now (Figure 7G). Figure 7H presents the simplest model consistent with these data. In this model, lateral excitation is local and presynaptic to the LGMD, whereas lateral inhibition (Figure 4) is upstream, as is global inhibition (Figure 6).

DISCUSSION

Little is known about how networks converging onto collision-detecting neurons are wired to shape their selectivity. Using calcium imaging, we investigated how connectivity among presynaptic excitatory inputs to the LGMD shapes its responses. We provide evidence for two types of connectivity patterns: lateral excitation and global (normalizing) inhibition. Lateral excitation promotes responses to coherently expanding stimuli, tuning the neuron to its preferred features. Global inhibition likely keeps excitation within the dynamic range of the neuron. Together with DL inhibition suppressing background motion noise (O’Shea and Rowell, 1975), these experiments show that the presynaptic interactions among excitatory inputs to the LGMD are governed by a complex, but interpretable, set of rules.

Calcium imaging was effective at establishing the excitatory effect of muscarinic acetylcholine receptors on synaptic excitation to the LGMD. These excitatory interactions could not be evidenced in earlier experiments where only two adjacent ommatidia were stimulated (Jones and Gabbiani, 2010; Zhu and Gabbiani, 2016). Earlier experiments showed that blocking nicotinic acetylcholine receptors abolished calcium responses in LGMD dendrites upon subsequent iontophoresis of acetylcholine (Peron et al., 2009; Figure S1). This suggests that LGMD dendrites do not possess excitatory muscarinic acetylcholine receptors because their effects usually rely on calcium signaling.

In mammals, 5 types of muscarinic acetylcholine receptors (m1–m5) have been found, of which m1, m3, and m5 are coupled to G protein members of the Gq/11 family, mostly resulting in excitatory effects. Two other muscarinic acetylcholine receptor types (m2 and m4) couple to G proteins of the Gi/0 family, which leads to presynaptic or postsynaptic inhibition (Caulfield, 1993; Brown, 2010). In flies and other arthropods, 3 types of muscarinic acetylcholine receptors have been found: types A, B, and C (Xia et al., 2016). Type A resembles most of the vertebrate muscarinic acetylcholine receptors and is activated by acetylcholine and muscarine and blocked by atropine and scopolamine. Type B is also activated by acetylcholine but insensitive to muscarine and not blocked by classical antagonists (Collin et al., 2013). The type A muscarinic acetylcholine receptor is coupled to Gq/11 type proteins, whereas type B is coupled to Gi (Ren et al., 2015). Type C resembles type A (Xia et al., 2016). Our results suggest that the muscarinic acetylcholine receptors presynaptic to the LGMD are either of type A or C. Their excitatory effects might result from inhibition of presynaptic M channels or other potassium channels (Brown, 2010). In Drosophila’s visual system, T4 and T5 cells, directionally selective neurons that synapse onto lobula plate tangential cells, both express transcripts of nicotinic and muscarinic acetylcholine receptors (Shinomiya et al., 2014). Although their role remains unknown, our results suggest that muscarinic acetylcholine receptor activation likely last >100 ms, a time relative to that relevant for directional motion detection (Behnia et al., 2014). However, muscarinic acetylcholine receptors may contribute to other visual detection tasks requiring local modulation of activity on a slow timescale.

The most likely localization of muscarinic acetylcholine receptors is between adjacent presynaptic terminals of the LGMD because these synapses are cholinergic, and none have been reported elsewhere (Rind et al., 2016). Because of the retinotopic projection of these axons onto LGMD dendrites, their effects would have to be local (Figure 7H). This is consistent with the coherence-dependent effect of scopolamine (Figures 7A–7E). Our results do not rule out that some lateral presynaptic connections between LGMD excitatory afferents could be inhibitory. If this were the case, these inhibitory synapses would be considerably weaker than the excitatory ones because we could not detect any decrease in postsynaptic calcium upon muscarine application. Such inhibitory synapses could not be GABAergic (Rind and Simmons, 1998) and could not implement lateral inhibition if cholinergic (Figure 4).

Our experiments yielded several unexpected results. First, calcium activation outlasted the time interval over which a looming stimulus swept across the retinotopic region associated with a given dendritic branch. At the dendritic looming center, relative fluorescence changes outlasted the stimulus by as much as 1 s (Figures 1B and 1C). Two observations help explain this. First, the continued rise of dF/F immediately after the stimulus has left the red-shaded region in Figures 1B and 1C is caused in part by overlapped dendritic activation (red double arrow in Figure 1C; Zhu and Gabbiani, 2016). Second, although the horizontal edges of the stimulus leave the retinotopic region associated with the dendritic looming center, its vertical edges continue to stimulate the same dendritic branch and, thus, cause additional calcium entry (Figures 5A and 5C). Although muscarine and scopolamine consistently affected the strength of calcium signals (Figure 3), their effect on rise time differed (Figures 3H and 3P). It thus remains unclear whether muscarinic excitatory lateral interactions also contribute to responses beyond the region of dendritic overlap.

A second unexpected result was the excitatory nature of muscarinic acetylcholine receptor-mediated lateral interactions presynaptic to the LGMD. Up to now, the only demonstrated lateral interactions presynaptic to the LGMD were those of DL inhibition (O’Shea and Rowell, 1975). It was thus plausible that they would be implemented by the lateral connections evidenced at the level of the LGMD (Rind and Simmons, 1998).

(G) Earlier model with lateral inhibition presynaptic to the LGMD. The LGMD dendrites are shown at the bottom, TmAs in the center, and axonal terminals of lamina neurons at the top. The synapses of axonal terminals of adjacent TmAs are connected through inhibitory synapses (red arrows).
(H) Current model with lateral excitation presynaptic to the LGMD, normalizing inhibition, and upstream short-range lateral inhibition, with the same conventions as in (G). The exact locations of short-range lateral inhibition and global inhibition were not determined here, except that they are necessarily located upstream of the local lateral excitation.

In (B)–(E), n = 5.
Our results (Figures 4 and S4) indicate that this is not the case and that DL inhibition is most likely located further upstream.

A third unexpected result is the presence of size-dependent, global inhibition upstream of lateral excitation. Global inhibition explains why the dendritic activation width for an SL stimulus is smaller than that observed for an HBR stimulus or for a small translating stimulus. The function of global inhibition is likely to normalize the strength of the excitatory inputs impinging on the LGMD. As a looming stimulus expands, the number of activated ommatidia grows nearly exponentially, and the increase in edge velocity increases the strength of individual synaptic inputs as well (Jones and Gabbiani, 2010). Without normalization, excitation would grow more than $10^3$ fold. Global inhibition would normalize these inputs into the dynamic range of the LGMD. The results reported in Figure 1F are consistent with this hypothesis. A similar role for normalizing global inhibition has been documented in other sensory systems (Carandini and Heeger, 2011).

It is likely that several of our stimuli, particularly the larger ones, activated feedforward inhibition onto dendritic field C of the LGMD. Feedforward inhibition would hyperpolarize the membrane potential in dendritic field A and increase the calcium driving force and influx through nicotinic acetylcholine receptors. Consequently, our experiments likely underestimated the strength of global inhibition for such stimuli. Feedforward inhibition curtails the LGMD firing rate as the size of looming stimuli increases beyond an angular threshold (unpublished data). Our results suggest that global inhibition fulfills a different role (Wang et al., 2018).

Because lateral excitation is most likely local, requires activation of several neighboring ommatidia, and occurs on a relatively slow timescale, it might help discriminate between coherently and incoherently expanding looming stimuli. We confirmed this by showing that coherence sensitivity was diminished following blocking of lateral excitation (Figure 7). Local lateral excitation thus helps tune the LGMD to looming stimuli in addition to conductances located within the LGMD’s dendrites (Dewell and Gabbiani, 2018). However, presynaptic mechanisms play a somewhat smaller role (median coherence-specific reduction of 57% after blocking HCN channels, computed from Dewell and Gabbiani, 2018, versus 34% median specific reduction after scopolamine addition reported here).

These results have implications for other collision detection circuits. Particularly interesting will be to determine how they discriminate between coherent and incoherent looming stimuli and whether the biophysical mechanisms involved resemble those implemented in the locust visual system.

**EXPERIMENTAL PROCEDURES**

**Preparation**

Experiments were carried out on locusts 3–4 weeks past the final molt. Animals were mounted dorsal side up on a custom holder with their heads rotated 90° to make the anterior side point downward. The head and neck were bathed in locust saline, except for the right eye, which was used for visual stimulation. The head capsule was opened dorso-frontally between the two eyes. The gut and the muscles in the head capsule were removed to reduce brain movement. The head was detached from the body, leaving only the two nerve cords and 4 tracheas attached. The right optic lobe was desheathed with fine forceps. A metal holder was placed under the brain and the right optic lobe to elevate and stabilize them.

**Visual Stimulation**

Visual stimuli were generated with the Psychtoolbox (PTB-3) and MATLAB (MathWorks, Natick, MA). A digital light processing projector (DLP LightCrafter 4500, Texas Instruments, Dallas, TX) and a diffuser screen (non-adhesive stencil film, 0.1 mm thick) were used to provide the visual stimuli. The projector was programmed in pattern sequence mode with bitmap images in green color, which achieved a refresh rate of 243 Hz. The brightness of the display before presenting looming stimuli was 38.7 cd/m². The screen brightness at the level used for off stimuli was 0.06 cd/m². The brightness of the screen was calibrated and linearized by loading a normalized gamma table to the Psycho box. The screen was placed 25 mm away from the locust eye and measured 79 × 79 mm. For the experiments presented in Figure 7, a cathode ray tube monitor refreshed at 200 frames/s was used for stimulus display. The monitor was calibrated to ensure linear, 6-bit resolution over luminance levels. A 100- to 120-s delay was used between stimuli, and locusts were repeatedly brushed and exposed to light flashes and high-frequency sounds to decrease habituation. Coarse looming stimuli were generated as in Dewell and Gabbiani (2018). Briefly, the stimulation monitor was first pixelated with a spatial resolution approximating that of the locust eye (2 × 2), referred to as coarse pixels. Each coarse pixel’s luminance followed the same time course as that elicited by the edge of the simulated approaching object sweeping over its area. To alter spatial coherence, a random two-dimensional Gaussian jitter with zero mean was added to each coarse pixel screen location. The jittered positions were rounded to the nearest available coarse pixel location on the screen to prevent coarse pixels from overlapping. The SD of the Gaussian was altered between 0° and 80° to control the amount of shifting and the resulting spatial coherence of the randomized stimulus.

**Staining with Calcium Indicators**

At the beginning of an experiment, the LGMD was impaled with a sharp intracellular electrode (230–300 MΩ) containing 3 µl of 2 M potassium chloride and 1 µL of 5 mM OGB-1 or OGB-SN (hexapotassium salt; Thermo Fisher Scientific, Waltham, MA). Because of the stronger signal amplitude of OGB-1 compared with OGB-SN, OGB-1 was used in all experiments that investigated the effects of muscarine or scopolamine. For other experiments, we used OGB-SN because its kinetics were faster than those of OGB-1 (Figure S2). The kinetics of both dyes have been characterized in controlled environments, but they are likely affected by parameters beyond our control in vivo (e.g., intracellular pH). Lanthanophoresis of OGB-1 or OGB-SN was achieved with current pulses of ~3 nA, alternating between 1 s on and 1 s off, that lasted 6 min. The pulses were delivered by an Axoclamp 2B amplifier (Molecular Devices, Sunnyvale, CA). The LGMD was identified through its 1:1 spike correspondence with that of the descending contralateral movement detector (DCMD) (O’Shea and Williams, 1974), recorded extracellularly from the nerve cord with hook electrodes.

**Imaging, Electrophysiology, Pharmacology, and Data Acquisition**

We employed wide-field calcium imaging during visual stimulation experiments. The calcium indicators were excited by a 100-W mercury short arc lamp, and the resulting fluorescence was measured by a charge-coupled device (CCD) camera at a frame rate of 5 Hz (Roliara XR, Qimaging, Surrey, BC, Canada). We used a 16 × 0.8 numerical aperture (NA) water immersion objective lens for imaging (CFI75 LDLW 16×W, Nikon Instruments), 3 to 5 trials were averaged for each stimulus.

Scopolamine and muscarine were prepared at 6 mM in locust saline containing fast green (0.5%) to visually monitor the affected region. They were pumped using a pneumatic picocum pump (PV830, WPI, Sarasota, FL). Injection pipettes had tip diameters of ~2 µm and were visually positioned between the excitatory dendritic field of the LGMD and its most superficial inhibitory field with a micromanipulator (fields A and C; O’Shea and Williams, 1974). Brief air pulses with a pressure of ~6 psi caused drug ejection into the optic lobe. Spread of fast green was monitored to ensure that drugs diffused through the excitatory dendritic field. The visual stimuli were presented with an inter-stimulus interval of 5–6 min. Muscarine was puffed immediately before each stimulus, provided 5 s after pressure ejection ended. Based on previous
calculations of drug dilution within the optic lobe (see Materials and Methods in Dewell and Gabbiani, 2018), our best estimate for the final drug concentration at the LGMD is ~100 μM.

Intracellular LGMD and extracellular DCMD recordings were performed simultaneously with calcium imaging in some animals. After identification of the location in the LGMD’s excitatory dendritic branches that had been stained with the calcium indicator OGB-5N or OGB-1, a sharp electrode (25 MΩ) containing 3 μL of 2 M potassium acetate, 0.5 M potassium chloride, and 0.1 mM Alexa 488 was inserted into the excitatory dendrites under a 16× objective lens for recording. Intracellular signals were amplified in bridge mode with an Axoclip 2B and an instrumental amplifier (Brownlee Precision 440; NeuroPhase, Palo Alto, CA). LGMD and DCMD signals were acquired with a sampling rate of 5 kHz by a data acquisition card (PCI 6110; National Instruments, Austin, TX).

Data Analysis

Data analysis was performed with MATLAB. The relative fluorescence change was calculated as dF/F(t) = (F(t) − F0)/F0, with the baseline fluorescence F0 being the average of the first 10 frames (2 s) before the visual stimulus. For peak dF/F spatial maps (e.g., Figure 3A), the value of dF/F at each pixel was calculated as the median over a 5 × 5 pixel area centered at the given pixel (0.9 μm/pixel). After median filtering, only suprathreshold pixels were used, defined as having a peak dF/F > 180% of the maximum noise of dF/F at that pixel. The maximum (baseline) noise at each pixel was computed as the maximum of the dF/F values within 2 s before the onset of the visual stimulus. The threshold value of 180% was selected to eliminate pixels resulting in falsely positive dF/F outside the dendritic branches based on earlier 2-photon imaging experiments with high spatial resolution (Zhu and Gabbiani, 2016). The peak dF/F at the pixels above threshold were retained and passed through a Gaussian filter with an SD of 5 pixels. In Figure 1D, we selected the threshold value (dashed line) to be well above the baseline noise level so that calcium signals were unambiguously increasing at those time points. The results in Figures 1E and 1F are robust to changes of the threshold.

To map the dendritic receptive fields of square flashes at 5 locations on the screen, we measured the peak dF/F in response to individual flashes. For this purpose, we filtered the pixels that were above the noise level, then computed the maximum of the peak dF/F over all the pixels, and retained pixels above 4% of the maximum. This additional thresholding step was necessary because of the small amplitude of peak dF/F in response to square flashes. The threshold was selected to eliminate falsely positive dF/F pixels outside of the dendritic branches. The branches that were covered by the retained pixels were taken to be the dendritic receptive fields of that square flash.

The principal axes of the peak dF/F spatial map were computed by scaling and rounding the intensity of the peak dF/F at each pixel into integers. We took these integers for each pixel as the number of identical data points with coordinates matching those of that pixel. We performed a principal-component analysis on these data points to extract the first and the second principal components. We rotated the peak dF/F spatial map to make the first or second principal axis horizontal and summed the values of peak dF/F along the vertical axis to get the projected values along each principal axis.

To make plots, the membrane potential was first median-filtered over a time window of 30 ms and down-sampled 100 times (to 50 Hz).

Statistics

For paired comparison of the control and scopolamine groups, we performed a nonparametric one-tailed Wilcoxon signed-rank test. For responses to small flashes (Figures S3K–S3M), a non-parametric Wilcoxon rank-sum test was conducted on the number of spikes in response to individual stimuli before and after addition of scopolamine. To compare statistical differences between the means of groups stimulated with gratings of varying separations, we performed a one-way ANOVA. For comparing the slopes of two regression lines, we performed an ANCOVA. A two-way ANOVA was performed to compare statistical differences between the control and the scopolamine/muscarinic groups, each of which had different levels (types of visual stimuli). For comparisons using paired t test, normality was tested with a Lilliefors test with an alpha level of 0.2. For responses to stimuli with varying coherence (Figures 7A–7E), all changes were normally distributed, and a paired t test was used. We use the abbreviation mad for maximal absolute deviation.

DATA AND SOFTWARE AVAILABILITY

Data and MATLAB code to recreate all figures reported in this paper are available at https://doi.org/10.17632/gnb84wkr49.1.

SUPPLEMENTAL INFORMATION

Supplemental Information includes six figures and two videos and can be found with this article online at https://doi.org/10.1016/j.celrep.2018.04.079.

Figure S1. Additional properties of calcium responses to small square and looming stimuli. Related to Figure 1.

(A) Response to a small square stimulus. Representative dF/F change elicited in a single dendritic branch by a 50 ms long, 8x8" square off flash (mean and sd of 5 trials in one animal). The red line indicates the timing of the stimulus.

(B) Timing of peak dF/F relative to stimulus peak time as a function of distance from dendritic looming center. Box plots of the distance from looming center at -0.22, -0.02, 0.18 s relative to stimulus peak time (**p<0.01, 2-sample t-test). Data pooled from 7 animals (58 dendritic branches).

Figure S2. Time course of calcium responses measured with the dyes OGB-1 or OGB-5N to looming stimuli of different size to speed ratios. Related to Figure 2.

(A) a: Excitatory dendritic field of the LGMD with selected dendritic branches indicated by different colors. b: time course of looming stimulus angular size. c: relative fluorescence change recorded with OGB-1. Each trace is colored to match the dendrite colors on left and is an average of 3 trials in one animal. The right inset is a zoomed-in view of the same traces.

(B) Same as (A), but for OGB-5N in a different animal.

(C) Excitatory dendritic field of the LGMD with selected dendritic branches indicated by different colors. White dashed lines indicated the location of the intracellular sharp electrode.

(D) a: time course of the angular size of the looming stimulus with l/|v| = 30 ms. b: membrane potential (V_m) in the LGMD excitatory dendrite is shown in black solid trace. Gray shading, standard deviation of 3 trials. Thin solid colored traces are the time courses of the average dF/F within the selected dendritic branches in (C). The inset is a zoomed-in view of the same traces. In (D-I) the blue dashed line is the start of the looming stimulus and the red dashed line is the time of maximal stimulus size. Projected collision would occur 20 ms after maximal stimulus size.

(E) Same analysis as in (D) but in response to a looming stimulus with l/|v| = 60 ms. Projected collision would occur 40 ms after maximal stimulus size.

(F) Same analysis as in (D) but in response to a looming stimulus with l/|v| = 120 ms. Projected collision would occur 80 ms after maximal stimulus size.

(G) Firing rate of the LGMD in response to a looming stimulus with l/|v| = 30 ms. Blue shading, standard deviation of 5 animals.

(H) Firing rate of the LGMD in response to a looming stimulus with l/|v| = 60 ms. Blue shading, standard deviation of 5 animals.

(I) Firing rate of the LGMD in response to a looming stimulus with l/|v| = 120 ms. Blue shading, standard deviation of 5 animals.

Figure S3. Analysis and quantification of calcium responses on the excitatory dendritic field of the LGMD in various experimental conditions. Related to Figure 3.

(A) Schematics of two display positions in front of the locust eye with an angle difference of 30°. The ipsilateral LGMD neuron is depicted schematically (black arrow). The other eye is blocked by wax.

(B) Activation on the excitatory dendritic field in response to looming stimuli (l/|v| = 120 ms) simulating approach from two different angles, as in (A), is shown in the left and right panels, respectively. Each black cross indicates the center-of-mass of the activation on the excitatory dendritic field.

(C) The two principal axes of the activated area on the excitatory dendritic field for the data shown on the left panel in (B). The red and blue arrows indicate the 1st and 2nd principal axis, respectively.

(D) a: sum of peak dF/F projected onto the first principal axis and plotted as a function of the projection location along the first principal axis (n = 1 animal, 1 looming angle/animal). b: same analysis as a but after normalization to the peak of the curve for each animal across animals. Thick line and red shading indicate the mean and the standard deviation (n = 5 animals, 2 looming angles/animal).

(E) a: sum of peak dF/F projected onto the second principal axis and plotted as a function of the projection location along the second principal axis (n = 1 animal, 1 looming angle/animal). b: same analysis as a but after normalization to the peak of the curve for each animal across animals. Thick line and blue shading indicate the mean and the standard deviation (n = 5 animals, 2 looming angles/animal).

(F) Comparison of the FWHM of the curve in (D) b and (E) b with the distance between the center-of-masses (COMs) in response to looming stimuli on displays with 30° in orientation difference (n=5 animals).
Figure S4. Test of the influence of muscarine on lateral inhibition. Related to Figure 4.

(A) a: activation on the LGMD excitatory dendritic field in response to the small translating visual stimulus (n=5). Note increased activation relative to control.

(B) Excitatory dendritic field of the LGMD with selected dendritic branches indicated by different colors.

(C) a: time courses of the average dF/F at each of the selected dendritic branches in (B), with matched colors, in response to a small translating visual stimulus as in Fig. 4A. Each trace is an average of dF/F over 3 trials. Black vertical dashed line: time when the small visual stimulus appears. Red vertical dashed line: time when the small visual stimulus starts translating. Blue vertical dashed line: time when the lateral gratings starts drifting and 0.2 s later the small visual stimulus moves completely outside of the display. The asterisk and plus markers on each curve indicate the baseline and the peak dF/F of the calcium response to the translating stimulus, respectively. b: For each dendritic branch the amplitude of dF/F is computed by subtracting the baseline (indicated by the plus marker) from the peak dF/F (indicated by the plus marker in a) for each curve in a with matched color and plotted as a function of the time at peak dF/F.

(D) a: time courses of the average dF/F (over 3 trials) at each of the selected dendritic branches in (B), with matched colors, in response to the small translating visual stimulus with lateral drifting gratings (with a separation of 50°) as in Fig. 4B. Black vertical dashed line: time when the small visual stimulus and lateral gratings appear. Red vertical dashed line: time when the lateral gratings starts drifting and 0.2 s later the small visual stimulus starts translating. Blue vertical dashed line: time when the small visual stimulus moves completely outside of the display and the lateral gratings stop moving. The asterisk and plus markers on each curve indicate the baseline and the peak dF/F of the calcium response to the translating stimulus, respectively. b: For each dendritic branch the amplitude of dF/F is computed by subtracting the baseline (indicated by the asterisk marker in a) from the peak dF/F (indicated by the plus marker in a) for each curve in a with matched color and plotted as a function of the time at peak dF/F.

(E) Same visual stimuli and plotting conventions as in (C), after puffing muscarine. Note decreased dF/F relative to (C).

(F) Same visual stimuli and plotting conventions as in (D), after puffing muscarine. Note decreased dF/F relative to (E), suggesting lateral inhibition is unaffected by mAChRs.

(G) The amplitude of dF/F on every selected dendritic branch after puffing muscarine versus before puffing (5 animals, 47 dendritic branches total, average of 3 trials per condition). Purple dots: small translating stimuli with no drifting lateral gratings. Green, light green, red, and blue dots: small translating stimuli with drifting lateral gratings separated by 70°, 50°, 30° and 7.5°, respectively. Purple, green, light green, red and blue diamonds are the mean (center-of-mass) of the purple, green, light green, red and blue dots, respectively. No change in dF/F was observed after puffing muscarine.

(H) Time at peak dF/F on every selected dendritic branch after versus before puffing muscarine. Same plotting conventions as in (G). No change in peak timing was observed.

(I) Box plots of the mean amplitudes of dF/F for all the branches in each animal in response to small translating stimuli with no drifting lateral gratings, and with gratings separated by 70°, 50°, 30° and 7.5°, respectively. Blue, after puffing muscarine. Magenta, before puffing muscarine (n=5 animals; p=0.0004 for control and p=0.001 for muscarine, one-way ANOVA; p=0.07 for control vs. muscarine, two-way ANOVA). Note decreased dF/F with grating separation, consistent with lateral inhibition.
Figure S5. Calcium responses to looming stimuli restricted to horizontal and vertical bands after puffing muscarine. Related to Figure 5.

(A) a: from left to right, schematics of a standard looming stimulus, a looming stimulus restricted in a horizontal band (along the dorsal-ventral eye axis) and in a vertical band (along the posterior-anterior eye axis), respectively. b: from left to right, activation on the LGMD excitatory dendrite in response to the same stimuli after puffing muscarine. Same neuron as in Fig. 5A. Note increased dF/F for all stimuli.

(B) a: three selected ROIs on different dendritic branches. The center region represented in red mapped to the looming center. The two blue regions are approximately symmetrically placed on either side of the center region along the 1st principal axis. b: peak dF/F in the center or surrounding ROIs for standard, horizontal and vertical band-restricted looming before puffing muscarine. c: the ratio of mean peak dF/F of the center branches (red, corresponding to the region selected in red in a) and surrounding branches (blue, corresponding to the region selected in blue in a) after puffing muscarine to that before puffing in response to the standard looming stimulus, the looming stimulus restricted in a horizontal band, or restricted in a vertical band, respectively. (n=5 animals, *p<0.05, n.s.: not significant, i.e., p>0.05, two-sample t-test assuming unequal variances). Note increased responses, but unchanged gain between center and surrounding regions for all stimuli.

(C) Same analyses as in (B) except for the selection of two regions (in blue) approximately symmetrically placed on either side of the center region (in red) along the same dendritic branch (corresponding approximately to 2nd principal axis). Note increased dF/F for all stimuli (b), but unchanged gain (c).

(D) a: 8 selected regions-of-interest (ROIs, same as in Fig. 5B) aligned with 1st principal axis are represented by different colors in an example LGMD neuron. White arrow points to the dendritic region that maps to the looming center. Red arrows indicate the 1st principal axis of the activated area during the looming response. b: peak dF/F in the 8 selected ROIs pooled across 5 animals in response to the standard looming stimulus (black crosses), the looming stimulus restricted in a horizontal band (red dots) or restricted in a vertical band (blue circles) after puffing muscarine. Solid lines are the linear regression of the data (n=5, *p<0.05, **p<0.01, ANCOVA test of slopes).

(E) Sum of peak dF/F projected onto the 1st (a) and 2nd (b) principal axes and plotted as a function of the projection location along that principal axis after normalizing to the peak of the curve in response to the standard looming stimulus (black), the looming stimulus restricted in a horizontal band (red) or restricted in a vertical band (blue) after puffing muscarine. Red, black and blue shadings, standard deviation of 5 animals. Note increase relative to control (Fig. 5C) and similarity of red and black lines in a and of blue and black lines in b.

(F) Box plots of the full-width at half-maximum (FWHM) of the curves in (E) along the first principal axis (a) and the second principal axis (b) in response to the standard or the horizontal/vertical band-restricted looming stimulus after puffing muscarine. The FWHM after puffing muscarine is significantly higher than that before puffing muscarine except for the looming stimulus restricted in a vertical band along the 2nd principal axis (n=5 animals, *p<0.05, **p<0.01, paired t-test, n.s., not significant, i.e., p>0.05). Note similarity of standard and hori. along 1st principal axis and of standard and vert. along 2nd principal axis, suggesting saturation of the responses after muscarine.

Figure S6. Comparison of dendritic activation area for small translating squares and looming stimuli. Related to Figure 5.

Sum of peak dF/F projected onto the 1st (a) and 2nd (b) principal axes and plotted as a function of the projection location along that principal axis after normalizing to the peak of the curve in response to the standard looming stimulus (blue), or a small translating square (red; same as stimuli in Fig. 4A). Solid lines are mean and shaded areas, standard deviations over 10 animals. The FWHM of the two stimuli along 1st principal axis are significantly different (p=8.37·10^{-5}), but those along the 2nd principal axis are not (p=0.14; two-sample t-test).
