Evaluation of Adhesive Behaviors of Chromium Nitride Coating Films Produced by Arc Ion Plating Method*

Ri-ichi MURAKAMI**, Yun-Hae KIM***, Kazushi KIMURA**, Daisuke YONEKURA** and Do-Hoon SHIN**

Scratch tests and pin-on-disk wear tests were performed to clarify the cracking and delaminating behavior of CrN coatings. The CrN films were coated onto an aluminum alloy substrate, JIS A2024, by an arc ion plating method. Eight types of single-layered coating and multilayered coatings were prepared by changing the bias voltage during the deposition. \( L_{CI} \) and \( L_{CH} \) values were not improved by increasing the number of layers. The critical loads of the single-layered coatings decreased with increasing the bias voltage. It appears that, for the multilayered coatings, the combination of bias voltages influenced the critical loads. The critical loads strongly depended on dynamic hardness and Young’s modulus. In particular, the critical loads of the multilayered coatings were influenced by the properties of the intermediate and bottom layers as well as the surface roughness, hardness and Young’s modulus of the top layer. The large film delamination for single-layered coatings deposited using a high bias voltage occurred during pin-on-disk wear tests even though the critical loads of the single-layered coatings were higher than those of the multilayered coatings. If the brittle top layer could be broken and delaminated by the sliding contact, the ductile bottom layer coated under a bias voltage of 0 V could endure the complete delamination of film.

Key Words: Scratch Test, Tribology, Aluminum Alloy, Arc Ion Plating, CrN, Thin Film

1. Introduction

Aluminum alloy is widely used for various machine parts because of its high specific strength and good workability. Because aluminum alloy also has a low wear resistance, its surface needs to be modified. Usually, the anodic oxidation method is applied to improve the wear resistance of aluminum alloy\(^{(1),(2)}\). The anodic oxidation method produces a highly hardened surface, but it is difficult to maintain the dimensional accuracy of the parts because of the marked change in dimensions.

Physical vapor deposition (PVD) methods are used to improve the tribological properties of working tools and machine parts. Because PVD coating is normally performed at 573 K, machine parts are scarcely influenced by the coating heat. TiN, CrN and diamond like carbon (DLC) films are coated by PVD coatings. CrN film has a good wear resistance\(^{(3),(4)}\), corrosion resistance\(^{(5),(6)}\), oxidation properties\(^{(7),(8)}\) and thermal stability\(^{(9)}\). Many researchers have studied the tribological properties of CrN\(^{(10)}\)–\(^{(12)}\). Martinez et al.\(^{(10)}\) have reported that for nanometric CrN/Cr multilayers, the tribological behavior depends on the film properties, coating-substrate interface and substrate mechanical properties. Lee et al.\(^{(11)}\) have predicted the wear life of a TiN coating using the results of indentation, scratch and repeated sliding tests.

In this study, CrN film has been deposited onto an aluminum alloy substrate under various bias voltages using an arc ion plating method. The influence of the bias voltage on the bonding strength between the CrN coating and the aluminum alloy substrate has been evaluated by a scratch test and a pin-on-disk wear test. Then the influence of the multilayered coating on the cracking and delamination of the film is discussed.

2. Experimental Procedure

The substrate material of the specimens was JIS A2024 T4 aluminum alloy containing HV 151. The chemical compositions of this material are 4.5% Cu, 1.5% Mg,
0.59% Mn, 0.28% Fe, 0.11% Si, 0.02% Cr, 0.02% Zn, 0.02% Ti and 0.02% Ti+Zr. The substrate for coating was machined to a disk of 20 mm diameter and 10 mm height. Each specimen was mechanically polished using #150–#1500 emery papers and 0.02 μm colloidal silica, and then ultrasonically cleaned in acetone.

CrN film was deposited onto the substrate by the arc ion plating (AIP) method using AIP201 equipment (Kobe Steel Ltd.). For CrN film deposition, the specimen was put into a vacuum chamber, which was hung from a holder using stainless wire during deposition. The distance between the target and the specimen was 100 mm. After the vacuum chamber was evacuated using a vacuum pump to \(3.3 \times 10^{-3}\) Pa, the deposition process was started. Details of the deposition process are as follows: Firstly, the specimen surface is cleaned up by ion bombardment at a bias voltage of \(-700\) V for 1 min with no heating. Then it is cooled in the chamber for 60 min because the temperature exceeds 373 K by ion bombardment. It is important during this cooling to maintain the temperature below approximately 473 K, which is the softening temperature of the aluminum alloy. The coating of CrN film was carried out three times using a Cr target (purity 99.99%) and nitrogen gas. Negative bias voltage was applied to the substrate during the coating process. The coating conditions were an arc current of 60 A, a nitrogen gas pressure of 3.0 Pa and a bias voltage of 0–60 V. Each coating process was carried out for 30 min with subsequent cooling for 120 min. Furthermore, multilayered films of CrN were produced by changing the bias voltage in each coating. The coating conditions and film thickness are shown in Table 1. For sample Nos. 1–4, the CrN films were coated under a constant bias voltage. For sample Nos. 5–8, the multilayered CrN films were coated using various bias voltages for each layer. The temperature of the specimen, which was directly measured by a thermocouple attached to a dummy specimen in the vacuum chamber, was below 473 K during the coating process. Film thickness was measured using a surface profilometer (Vecco Instruments, Dektak®).

Surface roughness was measured using the surface profilometer. Hardness tests were performed using a Shimadzu dynamic ultra-microhardness tester (DUH201W) with a load of 49 mN and Young’s modulus of the film was calculated from the load-unload curve. Scratch testing was performed using a CSEM Revertest scratch tester with a conical-spherical diamond indenter (50 μm radius tip) and critical loads of cracking (Lc1) and of partial delamination of the film (Lc2) were determined by observation of scratch tracks.

Pin-on-disk wear tests were performed to estimate the tribological properties of the coatings. A bearing steel ball (JIS SUJ2) was selected for a pin 6 mm in diameter. Wear tests were performed under a sliding velocity of 250 mm/sec up to a sliding distance of 5 000 m unless film delamination occurred. The normal applied load was 10 N. Disc mass loss was measured using an electrical balance.

3. Experimental Results

3.1 Scratch test results

3.1.1 Single-layered coatings The scratch track images of single-layered coatings were observed by optical microscopy. Figure 1 shows features of modes I and II.
II in the scratch track for sample Nos. 1 – 4. In Fig. 1 (a) and (b), there are no cracks of mode I in the scratch track for sample Nos. 1 and 2 at 10 N. Figure 1 (c) and (d) indicate that, for sample Nos. 3 and 4, many semicircular cracks of mode I are clearly observed at 10 N in the scratch tracks. For sample Nos. 2 – 4, there are similar features of film delamination of mode II as shown in Fig. 1 (f) – (h). However, because for sample No. 1, only partial delamination occurs in the scratch track, LCII in mode II is higher for sample No. 1 than for the other samples, as shown in Fig. 1 (e).

Critical load was evaluated on the basis of optical microscopy observations. Figure 2 shows the critical load for single-layered coatings and multilayered coatings. In Fig. 2, gray columns indicate the critical load (LCI) for mode I and white columns indicate the critical load (LCII) for mode II. For single-layered coatings, when the bias voltage is low, sample Nos. 1 and 2 exhibit a high LCI. LCI decreases with increasing bias voltage. LCII, which indicates the partial film delamination load, also decreases with increasing bias voltage.

3.1.2 Multilayered coatings Figure 3 shows features of modes I and II in the scratch track for multilayered coatings. There are different features of scratch tracks between the single-layered coatings and the multilayered coatings. For sample No. 5, the collapse of film indicated by mode I is observed on both borders of the scratch track with many cracks. Sample No. 6 shows many cracks of mode I but there is no collapse on both borders. The cracking behavior of mode I for sample No. 7 is quite different from those for sample Nos. 5 and 6. The distance between adjacent cracks for sample No. 7 is approximately 40 – 50 µm. This is larger for sample No. 7 than for sample Nos. 5 and 6 in which the crack distance is less than 5 µm. For sample No. 8, the scratching feature is similar to that of sample No. 1 which was coated under nonbias voltage. The film delaminations of mode II for multilayered coatings are shown in Fig. 3 (e) – (h). These features are similar to those of the single-layered coatings of sample Nos. 2 – 4.

Figure 2 shows also the critical loads of scratch tests for multilayered coatings. As shown in Fig. 2, the results sample Nos. 5 – 7 show that LCI and LCII values are not improved by increasing the number of layers. However, LCI and LCII values are higher for sample No. 8 than for sample Nos. 2 – 4 but these critical loads are still less than that of sample No. 1 (single-layered coating) coated under a nonbias voltage. For 0, 30 and 60 V combinations, the change in bias voltage clearly results in an increase in LCI. While, the critical loads for 20, 40 and 60 V combinations are scarcely influenced by coating order.

3.2 Surface morphology

3.2.1 Single-layered coatings Figure 4 shows SEM images of all the coating samples and their surface features.
roughness values. Figure 4 (a)–(d) are for the single-layered surface and Fig. 4 (e)–(h) are for the multilayered surface. The film surfaces of sample Nos. 3 and 4 are smooth and few droplets of white spherical particles are observed, as shown in Fig. 4 (c) and (d). In contrast, when bias voltage decreases, many droplets are observed on the film surface, as shown in Fig. 4 (a) and (b). In particular, the film surface of 0 V is always covered by small particles with sharp edges (Fig. 4 (a)). The surface roughness $R_a$ tends to increase with decreasing bias voltage, this would be caused by the difference in droplet distribution. AFM observation was performed on the single-layered films. The AFM observation results are shown in Fig. 5. It is obvious that the CrN films coated under the bias voltages of 40 V and 60 V have smooth surfaces and only a few particles are observed on the film surfaces. Thus, the bias voltage strongly affects the nanosized surface morphology of the film even though the difference in surface roughness is small.

### 3.2.2 Multilayered coatings

For multilayered coatings, the film surface morphology depends on the bias voltage of the top layer. When the bias voltage of the top layer increases, the film surface becomes smooth. However, the influence of bias voltage on surface roughness is smaller than that in the case of a single layer.

#### 3.3 Hardness and Young’s modulus

The hardness and Young’s modulus of the CrN film were measured using a dynamic ultra-microhardness tester. These results were obtained by averaging 20 points. Figures 6 and 7 show the dynamic hardness and Young’s modulus of single- and multilayered coatings, respectively. In the case of single-layered coatings (Nos. 1–4), dynamic hardness increases with bias voltage. The dynamic hardness for bias voltage of $-60$ V is threefold that of $0$ V bias voltage. In the case of multilayered coating (sample Nos. 5–8), surface hardness strongly depends on the top layer condition. For example, when the top layer is coated under 60 V (sample No. 6), the dynamic hardness is the highest value, while sample No. 8 of which the top layer coating is $0$ V has the lowest value. Dynamic hardness and surface morphology strongly depend on the bias voltage of the top layer. The dynamic hardness of multi-
layered coatings is also influenced by the combination of bias voltages. Although sample Nos. 6 and 7 are coated under the same top layer condition (60 V), sample No. 7, where the intermediate and bottom layers were coated under the low bias voltage of 30 V and 0 V, has a lower hardness than sample No. 6 having interlayers coated under 40 V and 20 V. These hardness properties result from the decreases in the hardness of the intermediate and bottom layers.

Young’s modulus shows the same behavior as dynamic hardness. For single-layer coatings (sample Nos. 1 – 4), a higher bias voltage coating exhibits a higher Young’s modulus. For multilayer coatings (sample Nos. 5 – 8), Young’s modulus depends on the combination of bias voltages.

### 3.4 Tribological properties

The pin-on-disk friction and wear test results are summarized in Table 2. Most of the samples were tested to 5 000 m without delamination of the film. However, the tests of sample Nos. 3 and 4 were stopped at a sliding distance of less than 100 m because the macroscopic delamination of the films occurred, as shown in Fig. 8. For sample Nos. 3 and 4, the films were fractured brittlely and collapsed by the sliding contact of the ball. The shape of the delamination edge was semicircular and film delamination occurred along the sliding direction. It is considered that the film was deformed by normal load and then the film was broken by bending stress. It appears that the film fracture and delamination for sample Nos. 3 and 4 were related to their low critical load, as shown in Fig. 2. However, although the critical loads of sample No. 7 were lower than those of sample Nos. 3 and 4, the crack and delamination sample was not observed in the wear track of sample No. 7.

Sample Nos. 2 and 5 – 8 showed almost the same specific wear rate as the ball. Only for sample No. 1 was a high wear rate obtained. The specific wear rate for multilayered coating disks was influenced by the combination of bias voltages and the surface conditions of the top layer. In the case of multilayered disks, wear rate de-

* film fractured by sliding distance of 100 m
creased when the top layer was deposited under a high bias voltage (sample Nos. 6 and 7). However, for the single-layered coatings, wear rate increased with bias voltage.

4. Discussion

4.1 Influence of bias voltage on scratch behavior

As shown in Fig. 2, it is clear from the scratch test data that bias voltage strongly influences the critical loads of the single-layered coatings. High-bias-voltage deposition results in a decrease in critical load. Dynamic hardness and Young’s modulus are also affected by bias voltage, as shown in Figs. 6 and 7. Therefore, it is considered that the critical loads depend on the dynamic hardness and Young’s modulus of CrN film. Figure 9 shows the relationship between dynamic hardness and critical load for single-layered coatings. Both \( L_{CI} \) and \( L_{CII} \) are markedly reduced to 6.6 N and 14.2 N, respectively, when dynamic hardness increases. When the dynamic hardness \( DH \) is over 800, these values hardly depend on dynamic hardness. Figure 10 shows the relationship between critical load and Young’s modulus for single-layered coatings. The critical loads of \( L_{CI} \) and \( L_{CII} \) values decrease with increasing Young’s modulus.

4.2 Influence of multilayered coatings on scratch behavior

The CrN films of sample Nos. 5 and 6 were coated under the same combination of bias voltages of 20, 40 and 60 V but under different deposition orders. The top layer of sample No. 5 was coated at 20 V. That of sample No. 6 was coated at 60 V. \( L_{CI} \) is slightly higher for sample No. 5 than for sample No. 6. \( L_{CII} \) value is also higher for sample No. 6 than for sample No. 5, as shown in Fig. 2. Sample Nos. 7 and 8 were coated under the same combination of bias voltages of 60, 30 and 0 V. As shown in Fig. 2, there is a difference in critical load between sample Nos. 7 and 8. \( L_{CI} \) and \( L_{CII} \) values are clearly higher for sample No. 8 than for sample No. 7. These result from the coating conditions of the top layer because the top layer of sample No. 7 was coated under 60 V and the top layer of No. 8 sample was coated under 0 V. It appears that the combinations of bias voltages such as 20, 40 and 60 V and 0, 30 and 60 V result in the difference in mechanical properties between each layer. Figures 11 and 12 show the relationship between critical load and dynamic hardness, and the relationship between critical load and Young’s modulus, respectively. It is clear from Figs. 11 and 12 that \( L_{CI} \) decreases with increasing dynamic hardness and Young’s modulus, regardless of the combination of bias voltage. However, the relationship between \( L_{CII} \) and dynamic hardness or Young’s modulus differs with respect to the coating combination. For sample Nos. 7 and 8, \( L_{CII} \) decreases with increasing the dynamic hardness and Young’s modulus. While, for sample Nos. 5 and 6 that value slightly increases with increasing dynamic hardness and Young’s modulus. It appears that though the top layer coated under 0 V decreases the dynamic hardness and Young’s modulus, the top layer contributes to the increase in \( L_{CII} \) value. The critical load of sample No. 7 is lower than those of
Nos. 5 and 6, as shown in Figs. 2, 11 and 12. For sample No. 7, large delamination of film was not observed during the pin-on-disk wear test. This fact suggests that if the brittle top layer would be broken and delaminated by the sliding contact, the ductile bottom layer coated under a bias voltage of 0 V may endure the complete delamination of film.

5. Conclusions

Scratch tests and pin-on-disk wear tests were performed to clarify the cracking and delaminating properties of CrN coatings. The CrN film was coated onto an aluminum alloy substrate by the arc ion plating method. The obtained results can be summarized as follows.

(1) The LCI of the single-layered coatings decreased with increasing bias voltage. The critical load at the partial delamination, LCI, also decreased with increasing bias voltage. LCI and LCI did not improve by multilayered deposition, but the influence of the combination of bias voltages clearly appeared for critical loads.

(2) In the case of single-layered coatings, the dynamic hardness and Young’s modulus of the CrN film increased with increasing bias voltage. In the case of multilayered coatings, the roughness, hardness and Young’s modulus were strongly affected by the properties of the top layer and were also influenced by the deposition order.

(3) Both LCI and LCI of the single layered coatings markedly decreased with increasing dynamic hardness. The correlation of Young’s modulus with critical load was similar to the case of the dynamic hardness.

(4) The surface hardness and Young’s modulus of the multilayered coatings have a strong influence on LCI regardless of the combination of bias voltages. LCI was influenced by the mechanical properties of the top layer and the combination of each layer.

(5) Although the critical loads of 40 V and 60 V single-layered coatings were higher than those of multilayered coatings with 60 V top, 30 V intermediate and 0 V bottom layers, large delamination occurred for single-layered coatings during the pin-on-disk tribological test. The top layer could be broken and delaminated by the sliding contact, because of its brittle property. However, since the bottom layer was coated under 0 V, the bottom layer might have ductility and flexibility and might endure the complete delamination of film.
