ABSTRACT

Amorphous alumina films containing gold nanoparticles were grown by radio frequency (rf) magnetron sputtering technique, with a variation of area ratio of gold/Alumina target (rAu/Al₂O₃). Effect of the gold content in the composite films on the microstructural and optical absorption have been investigated. From the X-ray diffraction (XRD) measurements, the texture coefficient, lattice parameters and grain size and strain were calculated and correlated with changing rAu/Al₂O₃. Contrary to the melting point of free metal cluster, it is found that melting point of gold nanoparticles embedded in amorphous alumina matrix is larger than the melting point of the corresponding bulk material, decreases with increasing size of particles. The surface plasmon resonance peak wavelength, volume fraction and size of gold nanoparticles were determined from the optical absorption spectra of the samples through the Maxwell-Garnett effective model fitting, considering the size dependent mean free path limitation of free electrons. The peak wavelength of the surface plasmon resonance (SPR) was found to redshift from 500 nm to 558 nm and size increases from 2.2 nm to 5.8 nm when the rAu/Al₂O₃ increases from 1.3% to 2.6%, and remain at the same wavelength for larger size.

1. Introduction

In the last decades, noble metal nanoparticles attracted considerable attention by scientific community, which is connected with their strong localized surface plasmon resonance (LSPR) that appears at optical frequencies. The (LSP) are quantized collective oscillations of conduction electrons against the positive ionic background in the presence of electromagnetic wave that can enhance and focus incident light to sub-wavelength dimension below the diffraction limit [1]. Surface plasmon resonance (SPR) technique is getting great attraction in sensor technology since it can be used for the detection of various physical, chemical and biological parameters [2–5]. The key parameter of such materials is often the position of the plasmon resonance peak that can be tuned over a wide spectral region by the NPs size and shape, their distance, by the surrounding dielectric environment of nanoparticles and, naturally by the metal type [6,7]. By tuning these parameters, the resonance frequency can be matched to any desired wavelength from visible to near-infrared region [8,9]. Therefore, by detecting the LSPR shift with refractive index/dielectric constant of surrounding medium, metal nanoparticles can be used as plasmonic sensors [6–9].

So far, various deposition techniques have been employed to fabricate Au/Al₂O₃ thin films including ion implantation [10], sol-gel [11], Laser evaporation [12], and RF magnetron sputtering [13–16]. Among these techniques, RF magnetron sputtering takes the advantage of strong adhesion between film and substrate, large area deposition and low substrate temperature. However, various deposition parameters such as argon pressure, the variety of sputtering target, and sputtering power may influence the properties of the films. Furthermore, much attention has been paid to the changes of volume fraction of metal nanoparticles, and the composite of nanoparticles embedded in various matrices (TiO₂, ZnO, BaTiO₃, SiO₂ and so on) for single metal dispersed composite films [17–22]. In our previous work [16], we studied the effect of argon pressure on the concentration of gold nanoparticles dispersed in an alumina matrix. The present work focuses on the investigation of the influence of sputtering area ratio of Au/Al₂O₃ for the target (rAu/Al₂O₃) on the concentration, structural and optical properties of nanocomposite films deposited by RF-magnetron sputtering. The deposited composite films were examined by X-ray diffraction and optical absorption spectroscopy.

2. Experimental Methods

The samples studied, consisting of Au/Al₂O₃ composite thin films on clean glass substrates, were prepared at room temperature by RF magnetron sputtering technique using an Alcatel SCM 650 apparatus. The target is constituted by two materials: an alumina disc of purity 99.99%, with a diameter of 50 mm, over which chips of gold covering a fraction area (rAu/Al₂O₃), were placed on top of alumina disc. The chamber was evacuated to a pressure better than 10⁻⁶ mbar before the argon gas for the sputtering was introduced. Deposition was carried out at a fixed argon pressure 10x10⁻³ mbar, and at 1.3%, 2.6%, 10.5%, of gold-to-alumina surface ratio, of materials from which the composite film is fabricated. The deposition of all the samples was performed at a fixed substrate to target distance, deposition time and applied power at 60 mm, 4 h 30 min and 50 W, respectively. Under these conditions, three sets of samples are prepared and they are denoted as: A₁ (rAu/Al₂O₃ = 1.3%), A (rAu/Al₂O₃ = 2.6%) and A₃ (rAu/Al₂O₃ = 10.5%).

X-ray diffraction analyses were performed in a Philips PW 1710 spectrometer using CuKα radiation (λ = 1.54056 Å) and a Bragg-Brentano geometry. The diffraction patterns were collected over the range 2θ = 10° to 80° at room temperature. Optical absorption spectra, of Au/Al₂O₃ composite films, were registered by a Shimadzu UV 30101 PC spectrometer, in near ultra-violet-visible-near infra-red range (NIV-VIS-NIR) from 300 to 2000 nm.

3. Results and Discussion

3.1 Structural Characterization

Fig. 1 shows the XRD patterns of Au/Al₂O₃ composite films deposited at fixed argon pressure 10x10⁻³ mbar with a variation of the gold/alumina surface ratio ranging from 1.3% to 10.5%. X-ray diffraction patterns of gold thin film with a cubic structure, presented as a reference, is also reported in Fig. 1. For the sample deposited with rAu/Al₂O₃ = 1.3%, it is not obvious...
Au or SiO₂ crystalline peak in the spectra, but there is a weak diffraction peak at around 38° and a broad peak at around 64°, that corresponds to small gold nanoparticles embedded in amorphous alumina films. The intensity of Au peaks increases with increasing $r_{Au/AlO_2}$. In order to determine the phase structure, size and lattice parameter of AuNPs embedded in alumina films deposited at various $r_{Au/AlO_2}$ deconvolution procedure of the XRD patterns, where the details are reported elsewhere [23], were used assuming Voigt functions in order to obtain the peak position, intensity, preferential growth of the crystalline phases and the full width at half maximum.

The curve fitting XRD spectrum of Al series is reported in Fig. 2. The diffraction peaks resulting from the fitting are attributed to the crystal planes of Au(111), Au (200) and Au (220). The peak positions are in agreement with the well-known data: JCPDS 04-0784 characteristic of the fcc cubic structure, indicating that the small gold particles should adopt a fcc-like structure. The samples deposited at $r_{Au/AlO_2} = 2.6\%$ and $r_{Au/AlO_2} = 10.3\%$ show four distinct peaks identical to the reference gold thin film. We can note that the peak around $2θ = 26°$, assigned to amorphous alumina, becomes broad and disappears when the $r_{Au/AlO_2}$ increases. This can be explained by the fact that the samples having a large gold/alumina surface ratio exhibit a metallic appearance.

Quantitative information concerning the preferential crystal orientation can be obtained from the texture coefficient ($T_r$) which is defined as in relation given by [24]:

$$T_r(hkI) = \frac{I(hkI)/I(002)}{\sum_{i=0}^{n} I(hkI)/I(002)}$$  \hspace{1cm} (1)

where $T_r(hkI)$ is the texture coefficient of the facet (hkI), $I(hkI)$ is the intensity of the (hkI) reflection of the sample under analysis, $I_{002}$ is the intensity of the (002) reflection of a polycrystalline bulk sample and $n$ is the number of reflections taken into account.

If $T_r(hkI) \approx 1$ for all the considered (hkI) planes then the particles are randomly oriented crystallites which are similar to the JCPDS references. If the values of $T_r(hkI)$ is greater than 1, it indicates that the abundance of grains is formed in a given [hkI] direction. If $0 < T_r(hkI) < 1$ it indicates that there is a lack of grains in that given direction. As $T_r(hkI)$ increases, the preferential growth of the crystallites in the direction perpendicular to the [hkI] plane is greater. The texture coefficients calculated from the respective XRD peaks using Eq (1) are shown in Table 1.

### Table 1: Texture coefficient for four crystallographic planes of the deposited samples

| XRD peak (h k l) | Intensity observed | Texture Coefficient $T_r(h k l)$ |
|----------------|-------------------|----------------------------------|
| Al(311)       | 100.00            | $A_1$ = 1.67, $A_2$ = 1.60       |
| Au(311)       | 100.00            | $A_1$ = 1.67, $A_2$ = 1.60       |
| Au(200)       | 39.11             | $A_1$ = 0.93, $A_2$ = 0.93       |
| Au(220)       | 27.43             | $A_1$ = 0.91, $A_2$ = 0.82       |
| Au(311)       | 3.41              | $A_1$ = 0.47, $A_2$ = 0.63       |

Fig. 1 X-ray diffractograms of Au/AlO₃ nanocomposite thin films deposited at various gold/alumina surface ratio and JCPDS of gold thin films

Fig. 2 Experimental diffractogram of the sample deposited at $r_{Au/AlO_2} = 1.3\%$ and their curve fitting where different pseudo-Voigt functions were taken into account

![Experimental Curve Fitting vs. Fitting Composition](image)

Fig. 3 Texture coefficient of Au/AlO₃ nanocomposites thin films particles calculated from XRD pattern

Fig. 3 shows the gold/alumina ratio dependence of the texture coefficient for the (111), (200), (220), and (311) planes. The (111) plane is dominant. However, the Au crystallites have a texture structure along the Au (111). For this, all structural parameters will be calculated along this direction. The crystallite size was estimated from the Debye-Scherer’s formula using the FWHM in radians of the Au (111) reflection:

$$D = \frac{k \lambda \beta \cos \theta_B}{4 \sin \theta_B}$$  \hspace{1cm} (2)

where $k$ is a constant (0.9), $D$ is the crystallite size (in nm), $\lambda$ is wavelength (0.15406 nm), $\beta$ is full width at half maximum (FWHM in radian) and $\theta_B$ is the Bragg diffraction angle. The strain, $\varepsilon$, in the Au/AlO₃ films is calculated from the well known Williamson-Hall relation [25]

$$\varepsilon = \frac{\beta \cos \theta_B}{4 \sin \theta_B}$$  \hspace{1cm} (3)

The changes in the structural parameters of AuNPs are reported in Table 2. The lattice parameter and the grain size increases, while the strain decreases with increasing $r_{Au/AlO_2}$. The negative sign of the strain indicates that the strain is compressive. The increase in AuNPs sizes is obviously due to the increases in the gold concentration.

### Table 2: Results of the curve fitting of the experimental diffractograms calculated from Au(111) reflections of the samples

| Samples | Bragg’s angle (2θ) | FWHM (degree) | Lattice parameter (Å) | Particle size (nm) | Strain $(\varepsilon \times 10^{-5})$ |
|---------|-------------------|---------------|-----------------------|-------------------|----------------------------------|
| 1.3%    | 38.57             | 9.07          | 4.039                 | 1.04              | -10.2                           |
| 2.0%    | 38.36             | 2.65          | 4.060                 | 3.17              | -3.7                            |
| 10.5%   | 38.12             | 1.14          | 4.085                 | 7.34              | -1.6                            |

By increasing $r_{Au/AlO_2}$ the strain decreases, and takes the values ($-11.2 \times 10^{-3}$), ($-3.7 \times 10^{-3}$) and ($-1.6 \times 10^{-3}$) for the $A_1$, $A_2$ and $A_3$ series respectively, implying that these series are contracted during the sputtering process.

Young’s modulus is one of the most fundamental parameter to depict the elasticity of a given material. It determines the basic elastic deformation capacity of a structure under a bear load. When the diameter of nanocrystals is in the scale of several nanometers, the Young’s modulus is quite different from that of bulk. In order to determine elastic deformation capacity of nanocrystals, it is necessary to study the size dependent Young’s modulus. Bhatt and Kumar [26] developed the relation to study the size and shape dependence of Young modulus of nanomaterials, which can be written as follows:

$$Y(\rho) = \frac{1 - N_s}{2\pi N_s}$$  \hspace{1cm} (4)

The Young modulus of nanomaterials with size $D$ is $(D/\rho, Y(\rho))$ is the elastic modulus of corresponding bulk material (78 GPa). $N_s$ is the number

of surface atoms and \( n \) is the total number of atoms. The value of \( \frac{N_s}{2n} \)
depends on the structure of the Nanomaterials. For spherical nanosolids
its value may be given by [27]:

\[
\frac{N_s}{2n} = \frac{2d}{D}
\]

(5)

where \( D \) is the diameter of spherical nanosolids and \( d \) the diameter of the
atom. For gold (\( d = 0.2884 \text{ nm} \)). The calculated values are given in Table 3.

| Samples Number | Young’s modulus (GPa) | Melting Temperature (°C) |
|----------------|-----------------------|--------------------------|
| \( A_1 \)      | 34.92                 | 1468                     |
| \( A_2 \)      | 63.84                 | 1177                     |
| \( A_3 \)      | 71.88                 | 1120                     |

Table 3 Young’s modulus and melting temperature of calculated from Au (111)
reflections of the samples

*Fig. 4* size dependence of young’s modulus of Au/Al₂O₃

Fig. 4 presents the size dependent Young’s modulus of Au-NPs. We can
observe that Young’s modulus decreases as the particle size decreases. It is
clear from Fig. 4 that the size effect on Young’s modulus is more and
more obvious with the decrease in particle size. Its value increases from
34.92 GPa to 71.88 GPa when the size varies from 1.04 nm to 7.34 nm.

Thermodynamic properties which are essential in utilizing nanomaterials in some fields applications such as microelectronics,
nonlinear optics and solar energy, have garnered considerable attentions.
Among these properties, melting point is the most practical property in
NPs applications. It was reported in many works, for free standing NPs
[28-30], that the melting point decreases with decreasing size of NPs.
However, for the embedded NPs the melting point is not only related to
NPs’ size, structure and shape; but also affected by the embedding matrix.
For some matrices, melting of the embedded NPs occurs in lower temperature
than its bulk state, while it is possible for the same NPs to have
superheating above the melting point in some other matrices [31-35]. Qi et al. [36]
have developed a new model to accounting for the size and shape dependent
superheating of nanoparticles embedded in a matrix where the particle shape is considered by introducing a shape factor.
Melting temperature \( T_m \) of nanoparticles embedded in a matrix can be
further written as [36]:

\[
T_m = T_{mb} \left[ 1 - \frac{3 \alpha}{2} \left( 1 - \frac{T_m}{T_{mb}} \right) \right]
\]

(6)

where \( T_{mb} \) is the melting temperature of the matrix (2054 °C for alumina),
\( T_m \) is the melting temperature of bulk pure metals (1064 °C for gold), \( D \) is
the diameter of nanosolid, \( d \) is the diameter of the atom and \( \alpha \) is the shape
factor. In our case, the nanoparticles are spherical, the form factor \( \alpha \) is
taken equal to 1. The changes of melting temperature with size of god
nanoparticles embedded in Al₂O₃ matrix were calculated using Eq. (6). The
values are reported in Table 3. The variation of the melting temperature
with the gold particle size is reported in Fig. 5. We can note that the melting
temperature of AuNPs embedded in amorphous alumina films decreases
from 1468 °C to 1120 °C, when gold particle size increases from 1.04 nm
to 7.34 nm, indicating that particles with smaller size melt at higher
temperature and not agree with the melting point of a free metal cluster
size where it is well known to increase with its size. Another interesting
observation is that the melting temperature values of all the samples
remains above the melting point of bulk gold.

### 3.2 Optical Characterization

It is well known that the noble metal nanoparticles exhibit characteristic optical properties due to surface plasmon resonance
of conductive electrons, which results in an absorption peak in the UV-Vis region. Fig. 6 shows the experimental optical absorbance spectra of
Au/Al₂O₃ three samples deposited at different \( r_{Au/Al₂O₃} \) values. A very
weak and large band absorption due to the surface plasmon resonance is
observed for sample deposited at lower gold to alumina surface ratio
(1.3%). The broadening of the related SPR peak may be due to the mean
free path effect as well as the influence of conduction electron collisions
with particle surfaces [37]. With increasing \( r_{Au/Al₂O₃} \) from 1.3% to 10.5%,
the SPR peak for the Au particles exhibited a significant redshift
accompanying the narrowing and increase in intensity of the spectra.

*Fig. 5* Melting temperature of Au/Al₂O₃ nanoparticles as a function of particle size

Using the well-known Maxwell-Garnett effective medium theory, the
optical absorption coefficient (\( \alpha \)) of the Au/Al₂O₃ composite samples was
calculated. M-G theory may be expressed as follow [38]:

\[
\alpha = \frac{4\pi}{\lambda} \sqrt{f\left(\epsilon_{eff} - \epsilon_1\right) / \epsilon_2}
\]

(7)

where \( \epsilon_{eff} \) and \( \epsilon_2 \) are the real and imaginary parts of the effective
dielectric function \( \epsilon_{eff} \) who satisfies the equation:

\[
f = \frac{\epsilon_{eff} - \epsilon_m}{\epsilon_{eff} + 2\epsilon_m}
\]

(8)

where \( \epsilon_m \) is the dielectric function of the matrix, \( f \) and \( \epsilon \) are the volume
fraction and dielectric function of the metallic particles. The dielectric function of Au was taken from the work of Palik [39]. The dependence
of the metal dielectric function on the size of the particles is taken into
account using the model presented by Hövel et al [40]:

\[
\epsilon(\lambda, D) = \epsilon_{bulk}(\lambda) + \frac{\omega_p^2}{\omega^2 + i\gamma_{bulk}} - \frac{\omega_p^2}{\omega^2 + i\gamma_{bulk}(\omega + i\gamma_{loss}/D)}
\]

(9)

where \( \epsilon_{bulk} \) is the bulk gold dielectric constant, \( \omega_p \), \( \gamma_{loss} \) and \( \gamma_{bulk} \) being
the metal plasma frequency, the Fermi velocity and the electron scattering
rates in the bulk respectively, and \( \lambda \) is a phenomenological parameter
including details of the scattering process. The values of these parameters
used in our simulation are those cited in the work [16]. The simulation and
the experimental plots are shown in Fig. 7-9. These fitting allowed us to
evaluate, the gold particle size, the wavelength \( \lambda_{max} \) of the SPR band
absorption spectra and Au volume fraction. The deduced parameters are
summarized in Table 4.

Cite this Article as: A. Belahmar, A. Chouiyakh, M. Fahoume, Effect of sputtering area ratio of gold/alumina target on microstructure and optical absorption properties of Au nanoparticles dispersed in amorphous alumina dielectric films, J. Thin Films Res. 1(1) (2017) 20-24.
enhanced peak in the samples with effective mean free path, that the size of Ag particles would also induce the shift of the SPR peak, but changed from 7% to 10.5%. When the concentration of gold to alumina surface ratio give rise to an increase in the size and volume fraction of AuNPs. The lattice parameter, strain, young modulus, melting point and SPR peak position of AuNPs were determined and discussed. It is found that the melting point of gold nanoparticles dispersed in amorphous alumina films is larger than the melting point of the bulk gold material, and decreases with increasing size of AuNPs. Optical absorption spectra have been successfully explained by Maxwell-Garnett theory, taking into account of limited free path of conduction electrons. With increasing the volume fraction of Au content from 7% to 30%, the position of the maximum of SPR band absorption of AuNPs exhibit a redshift from 500 nm to 558 nm and no obvious change was observed for the higher volume fraction up to 46%, indicating that the peak position wavelength of the SPR is not sensitive to the particle size into the range included between 5.8 nm and 7.8 nm.

From the Table 4, we know that by increasing the area ratio of gold/alumina for the target, the size of AuNPs increases as well as the volume fraction of gold. The size varies from 2.2 nm to 7.8 nm when the concentration changed from 7% to 46% when the TAu/Al2O3 increases from 1.3% to 10.5%. While the resonance peak position shows a redshift as the Au content increased from 7 to 30 vol%. Then, no obvious change in peak position is observed from 30 to 46 vol% of Au. Kreibig et al. [37] reported that the size of Ag particles would also induce the shift of the SPR peak, but the position of the SPR peak was independent of particle sizes as the particle diameters were between 4 nm and 15 nm. The independence of particle sizes on optical absorption of the colloid gold in photosensitive glasses was also reported as the particles were smaller than several hundred atoms [41, 42]. This was interpreted as collisions of the conduction electrons with the particle surface, which reduced their effective mean free path, that is, the free path effect. The redshift of the SPR peak in the samples with 7-30 vol% Au may be due to the size effect. The narrowed peak in the sample with 46 vol% of Au may be due to the enhanced intrinsic free electron oscillation inside metal particles [17].

4. Conclusion

In this work, nanocomposite Au/Al2O3 thin films were synthesized by sputtering technique and characterised by XRD and optical absorption measurements. Increase in gold to alumina surface ratio give rise to an increase in the size and volume fraction of AuNPs. The lattice parameter, strain, young modulus, melting point and SPR peak position of AuNPs were determined and discussed. It is found that the melting point of gold nanoparticles dispersed in amorphous alumina films is larger than the melting point of the bulk gold material, and decreases with increasing size of AuNPs. Optical absorption spectra have been successfully explained by Maxwell-Garnett theory, taking into account of limited free path of conduction electrons. With increasing the volume fraction of Au content from 7% to 30%, the position of the maximum of SPR band absorption of AuNPs exhibit a redshift from 500 nm to 558 nm and no obvious change was observed for the higher volume fraction up to 46%, indicating that the peak position wavelength of the SPR is not sensitive to the particle size into the range included between 5.8 nm and 7.8 nm.
