Hyperbolic Distance Matrices

Puoya Tabaghi ⋆ Ivan Dokmanić †

Abstract

Hyperbolic space is a natural setting for mining and visualizing data with hierarchical structure. In order to compute a hyperbolic embedding from comparison or similarity information, one has to solve a hyperbolic distance geometry problem. In this paper, we propose a unified framework to compute hyperbolic embeddings from an arbitrary mix of noisy metric and non-metric data. Our algorithms are based on semidefinite programming and the notion of a hyperbolic distance matrix, in many ways parallel to its famous Euclidean counterpart. A central ingredient we put forward is a semidefinite characterization of the hyperbolic Gramian – a matrix of Lorentzian inner products. This characterization allows us to formulate a semidefinite relaxation to efficiently compute hyperbolic embeddings in two stages: first, we complete and denoise the observed hyperbolic distance matrix; second, we propose a spectral factorization method to estimate the embedded points from the hyperbolic distance matrix. We show through numerical experiments how the flexibility to mix metric and non-metric constraints allows us to efficiently compute embeddings from arbitrary data.

1 INTRODUCTION

Hyperbolic space is roomy. It can embed hierarchical structures uniformly and with arbitrarily low distortion \[1,2\]. Euclidean space cannot achieve comparably low distortion even using an unbounded number of dimensions \[3\].

Embedding objects in hyperbolic spaces has found a myriad applications in exploratory science, from visualizing hierarchical structures such as social networks and link prediction for symbolic data \[4,5\] to natural language processing \[6,7\], brain networks \[8\], gene ontologies \[9\] and recommender systems \[10,11\].

Commonly in these applications, there is a tree-like data structure which encodes similarity between a number of entities. We experimentally observe some relational information about the structure and the data mining task is to find a geometric representation of the entities consistent with the experimental information. In other words, the task is to compute an embedding. This concept is closely related to the classical distance geometry problems and multidimensional scaling (MDS) \[12\] in Euclidean spaces \[13,14\].

The observations can be metric or non-metric. Metric observations convey (inexact) distances; for example, in internet distance embedding a small subset of nodes with complete distance information are used to estimate the remaining distances \[15\]. Non-metric observations tell us which pairs of entities are closer and which are further apart. The measure of closeness is typically derived from domain knowledge; for example, word embedding algorithms aim to relate semantically close words and their topics \[16,17\].

⋆ University of Illinois at Urbana-Champaign, USA †, University of Basel ⋆tabaghi2@illinois.edu, †ivan.dokmanic@unibas.ch
In scientific applications it is desirable to compute good low-dimensional hyperbolic embeddings. Insisting on low dimension not only facilitates visualization, but also promotes simple explanations of the phenomenon under study. However, in most works that leverage hyperbolic geometry the embedding technique is not the primary focus and the related computations are often ad hoc. The situation is different in the Euclidean case, where the notions of MDS, Euclidean distance matrices (EDMs) and their characterization in terms of positive semidefinite Gram matrices play a central role in the design and analysis of algorithms [13, 18].

In this paper, we focus on computing low-dimensional hyperbolic embeddings. While there exists a strong link between Euclidean geometry and positive (semi)definiteness, we prove that what we call hyperbolic distance matrices (HDMs) can also be characterized via semidefinite constraints. Unlike in the Euclidean case, the hyperbolic analogy of the Euclidean Gram matrix is a linear combination of two rank-constrained Gramians. Together with the new spectral factorization method to directly estimate the hyperbolic points, this characterization gives rise to flexible embedding algorithms which can handle diverse constraints and mix metric and non-metric data.

1.1 Related Work

The usefulness of hyperbolic space stems from its ability to efficiently represent the geometry of complex networks [19, 20]. Embedding metric graphs with underlying hyperbolic geometry has applications in word embedding [16, 17], geographic routing [21], routing in dynamical graphs [22], odor embedding [23], internet network embedding for delay estimation and server selection [15, 24], to name a few. In the literature such problems are known as hyperbolic multidimensional scaling [25].

There exist Riemann gradient-based approaches [26, 5, 7] which can be utilized to directly estimate such embedding for metric measurements [27]. We emphasize that these methods are iterative and only guaranteed to return a locally optimal solution. In Section 3.3 we prove a closed-form spectral factorization method that finds the points from an HDM.

Non-metric (or order) embedding has been proposed to learn visual-semantic hierarchies from ordered input pairs by embedding symbolic objects into a low-dimensional space [28]. In the Euclidean case, stochastic triplet embeddings [29], crowd kernels [30], and generalized non-metric MDS [31] are some well-known order embedding algorithms. For embedding hierarchical structures, Ganea et al. model order relations as a family of nested geodesically convex cones [32]. Zhou et. al. [23] show that odors can be efficiently embedded in hyperbolic space provided that the similarity between odors is based on the statistics of their cooccurrence within natural mixtures.

1.2 Contributions

We summarize our main contributions as follows:

- **Semidefinite characterization of HDMs**: We introduce HDMs as an elegant tool to formalize distance problems in hyperbolic space; this is analogous to Euclidean distance matrices (EDM). We derive a semidefinite characterization of HDMs by studying the properties of hyperbolic Gram matrices—matrices of Lorentzian (indefinite) inner products of points in a hyperbolic space.

- **A flexible algorithm for hyperbolic distance geometry problems (HDGPs)**: We use the semidefinite characterization to propose a flexible embedding algorithm based on semidefinite programming. It allows us to seamlessly combine metric and non-metric problems in one
framework and to handle a diverse set of constraints. The non-metric and metric measurements are imputed as linear and quadratic constraints.

- **Spectral factorization and projection:** We compute the final hyperbolic embeddings with a simple, closed-form spectral factorization method. We also propose a suboptimal method to find a low-rank approximation of the hyperbolic Gramian in the desired dimension.

### 1.3 Paper Organization

We first briefly review the analytical models of hyperbolic space and formalize hyperbolic distance geometry problems (HDGPs) in Section 2. Our framework is parallel with semidefinite approaches for Euclidean distance problems as per Table 1. In the 'Loid model, we define hyperbolic distance matrices to compactly encode hyperbolic distance measurements. We show that an HDM can be characterized in terms of the matrix of indefinite inner products, the hyperbolic Gramian. In Section 3, we propose a semidefinite representation of hyperbolic Gramians, and in turn HDMs. We cast HDGPs as rank-constrained semidefinite programs, which are then convexified by relaxing the rank constraints. We develop a spectral method to find a sub-optimal low-rank approximation of the hyperbolic Gramian, to the correct embedding dimension. Lastly, we propose a closed-form factorization method to estimate the embedded points. This framework lets us tackle a variety of embedding problems, as shown in Section 4 with real (odors) and synthetic (random trees) data. The proofs of propositions and derivations of proposed algorithms are given in the appendix.

### Notation

We use small letters for vectors, $x \in \mathbb{R}^m$, and capital letters for matrices, $X = (x_{i,j}) \in \mathbb{R}^{m \times n}$. We enumerate elements of $x \in \mathbb{R}^m$ as $x_0, \ldots, x_{m-1}$, and let $[M]$ be short for the set ${1, \ldots, M}$. We define the set of asymmetric pairs as $[M]_{as} = \{(m, n) : m < n, m, n \in [M]\}$. We denote the $m$-th standard basis vector in $\mathbb{R}^M$ by $e_m$, $m \in [M]$. The norms $\|X\|_F, \|X\|_2$, and $\|X\|_{1,2}$ are Frobenius, operator, and $\ell_2$ norm of column norms $\|x_i\|_1$, respectively. The empirical expectation of a random variable is denoted by $E_N[x] = \frac{1}{N} \sum_{n=1}^{N} x_n$. The projection matrix onto the span of top $r$ eigenvectors of $G \succeq 0$ is denoted by $P_r(G)$, where $G \succeq 0$ indicates that $G$ is positive semidefinite. Finally, 0 and 1 are all-zero and all-ones vectors of appropriate dimensions.

2 HYPERBOLIC DISTANCE GEOMETRY PROBLEMS

2.1 Hyperbolic Space

Hyperbolic space is a simply connected Riemannian manifold with constant negative curvature. In comparison, Euclidean and elliptic geometries are spaces with zero (flat) and constant positive curvatures. There are five isometric models for hyperbolic space: half-space ($\mathbb{H}^d$), Poincaré (interior of the disk) ($\mathbb{I}^d$), jemisphere ($\mathbb{J}^d$), Klein ($\mathbb{K}^d$), and 'Loid ($\mathbb{L}^d$) (Table 2 and Figure 1). Each provides unique insights into the properties of hyperbolic geometry.

In the machine learning community the most popular models of hyperbolic geometry are Poincaré and 'Loid. We work in the 'Loid model as it has a simple, tractable distance function. It lets us cast the HDGP (formally defined in Section 2.2) as a rank-constrained semidefinite program. Importantly, it also leads to a closed-form embedding by a spectral method. For better visualization, however, we map the final embedded points to the Poincaré model via the stereographic projection, see Sections 2.1.2 and 4.

![Figure 1: Models of hyperbolic space with level sets (colors) illustrating isometries.](image-url)
2.1.1 'Loid Model

Let $x$ and $y$ be vectors in $\mathbb{R}^{d+1}$ with $d \geq 1$. The Lorentzian inner product of $x$ and $y$ is defined as

$$\langle x, y \rangle = x^\top H y,$$  \hfill (1)

where

$$H = \begin{pmatrix} -1 & \mathbf{0}^\top \\ \mathbf{0} & I \end{pmatrix} \in \mathbb{R}^{(d+1) \times (d+1)}. \hfill (2)$$

This is an indefinite inner product on $\mathbb{R}^{d+1}$. The Lorentzian inner product has almost all the properties of ordinary inner products, except that

$$\|x\|_H^2 \overset{\text{def}}{=} \langle x, x \rangle$$

can be positive, zero, or negative. The vector space $\mathbb{R}^{d+1}$ equipped with the Lorentzian inner product (1) is called a Lorentzian $(d+1)$-space, and is denoted by $\mathbb{R}^{1,d}$. In a Lorentzian space we can define notions similar to the Gram matrix, adjoint, and unitary matrices known from Euclidean spaces as follows.

**Definition 1 (H-adjoint)**. The H-adjoint $R^\ast$ of an arbitrary matrix $R \in \mathbb{R}^{(d+1) \times (d+1)}$ is characterized by

$$[Rx, y] = [x, R^\ast y], \ \forall x, y \in \mathbb{R}^{d+1}.$$  \hfill (3)

Equivalently,

$$R^\ast = H^{-1} R^\top H.$$  \hfill (3)

**Definition 2 (H-unitary matrix)**. An invertible matrix $R$ is called H-unitary if $R^\ast = R^{-1}$.

The 'Loid model of $d$-dimensional hyperbolic space is a Riemannian manifold $L^d = (L^d, (g_x)_x)$, where

$$L^d = \left\{ x \in \mathbb{R}^{d+1} : \|x\|_H^2 = -1, x_0 > 0 \right\}$$

and $g_x = H$ is the Riemannian metric.

**Definition 3 (Lorentz Gramian, H-Gramian)**. Let the columns of $X = [x_1, x_2, \ldots, x_N]$ be the positions of $N$ points in $\mathbb{R}^{d+1}$ (resp. $L^d$). We define their corresponding Lorentz Gramian (resp. H-Gramian) as

$$G = ([x_i, x_j])_{i,j \in [N]} = X^\top H X$$

where $H$ is the indefinite matrix given by (2).

The subtle difference between the Lorentz Gramian (defined for points in $\mathbb{R}^{d+1}$) and the H-Gramian (defined only on the manifold $L^d \subset \mathbb{R}^{d+1}$) will be important for the low-rank projection and the spectral factorization steps in Section 3. The indefinite inner product (1) also determines the distance between $x, y \in L^d$, as

$$d(x, y) = \text{acosh}(-\langle x, y \rangle).$$  \hfill (4)
2.1.2 Poincaré Model

In the Poincaré model the points reside in the unit Euclidean ball, as shown in Table 2. The distance between \( x, y \in \mathbb{I}^d \) is given by

\[
d(x, y) = \text{acosh} \left( 1 + 2 \frac{\|x - y\|^2}{(1 - \|x\|^2)(1 - \|y\|^2)} \right).
\] (5)

The isometric map between the 'Loid and the Poincaré model, \( h: \mathbb{L}^d \to \mathbb{I}^d \) is called the stereographic projection. For \( y = h(x) \), we have

\[
y_i = \begin{cases} 
0, & i = 0 \\
\frac{x_{i+1}}{x_{i+1} + 1}, & i \neq 0.
\end{cases}
\] (6)

The inverse of stereographic projection is given by

\[
x = h^{-1} \left( \begin{bmatrix} 0 \\ y \end{bmatrix} \right) = \frac{1}{1 - \|y\|^2} \left[ 1 + \frac{\|y\|^2}{2y} \right].
\] (7)

The isometry between the 'Loid and Poincaré models makes them equivalent in their embedding capabilities. However, the Poincaré model facilitates visualization of the embedded points in a bounded disk, whereas the 'Loid model is an unbounded space.

2.2 Hyperbolic Distance Problems

In a metric hyperbolic distance problem, we want to find a point set \( x_1, \ldots, x_N \in \mathbb{L}^d \), such that

\[
d_{mn} = \text{acosh} \left( -[x_m, x_n] \right), \quad \text{for all } (m, n) \in C,
\]

for a subset of measured distances \( D = \{d_{mn} : (m, n) \in C \subseteq [N]_\text{as}^2 \} \).

In many applications we have access to the true distances only through an unknown non-linear map \( \tilde{d}_{mn} = \phi(d_{mn}) \); examples are connectivity strength of neurons [36] or odor co-occurrence statistics [23]. If all we know is that \( \phi(\cdot) \) is a monotonically increasing function, then only the ordinal information has remained intact,

\[
d_{kl} \leq d_{mn} \iff \tilde{d}_{kl} \leq \tilde{d}_{mn}.
\]

This leads to non-metric problems in which the measurements are in the form of binary comparisons [31].

**Definition 4.** For a set of binary distance comparisons of the form \( d_{kl} \leq d_{mn} \), we define the set of ordinal distance measurements as

\[
\mathcal{O} = \{(k, l, m, n) : d_{kl} \leq d_{mn}, (k, l), (m, n) \in [N]_\text{as}^2 \}.
\]

We are now in a position to give a unified definition of metric and non-metric embedding problems in a hyperbolic space.

**Problem 1.** A hyperbolic distance geometry problem aims to find \( x_1, \ldots, x_N \in \mathbb{L}^d \), given

- a subset of pairwise distances \( \mathcal{D} \) such that

\[
d_{mn} = d(x_m, x_n), \quad \text{for all } d_{mn} \in \mathcal{D}
\]
and/or a subset of ordinal distances measurements \( O \) such that

\[
d(x_{i_1}, x_{i_2}) \leq d(x_{i_3}, x_{i_4}), \quad \text{for all } i \in O.
\]

where \( d(x, y) = \text{acosh} \,(−[x, y]) \) and \( i = (i_1, i_2, i_3, i_4) \).

We denote the complete sets of metric and non-metric measurements by \( \mathcal{D}_c \) and \( \mathcal{O}_c \).

3 HYPERBOLIC DISTANCE MATRICES

We now introduce hyperbolic distance matrices in analogy with Euclidean distance matrices to compactly encode inter-point distances of a set of points \( x_1, \ldots, x_N \in \mathbb{L}^d \).

**Definition 5.** The hyperbolic distance matrix (HDM) corresponding to the list of points \( X = [x_1, \ldots, x_N] \in (\mathbb{L}^d)^N \) is defined as

\[
D = \mathcal{D}(X) = (d(x_i, x_j))_{i,j \in [N]}.
\]

The \( ij \)-th element of \( \mathcal{D}(X) \) is hyperbolic distance between \( x_i \) and \( x_j \), given by \( d(x_i, x_j) = \text{acosh} (−[x_i, x_j]) \) and for all \( i, j \in [N] \).

HDMs are characterized by Lorentzian inner products which allows us to leverage the definition of an H-Gramian (Definition 3). Given points \( x_1, \ldots, x_N \in \mathbb{L}^d \), we compactly write the HDM corresponding to \( G \) as

\[
D = \text{acosh}[-G], \quad \text{(8)}
\]

where \( \text{acosh}[\cdot] \) is an elementwise \( \text{acosh}(\cdot) \) operator.

We now state our first main result: a semidefinite characterization of H-Gramians. This is a key step in casting HDGPs as rank-constrained semidefinite programs.

**Proposition 1 (Semidefinite characterization of H-Gramian).** Let \( G \) be the hyperbolic Gram matrix for a set of points \( x_1, \ldots, x_N \in \mathbb{L}^d \). Then,

\[
G = G^+ - G^- \quad \text{where} \quad G^+, G^- \succeq 0, \quad \text{rank} \, G^+ \leq d, \quad \text{rank} \, G^- \leq 1, \quad \text{diag} \, G = -1, \quad e_i^T Ge_j \leq -1, \quad \forall i, j \in [N].
\]

Conversely, any matrix \( G \in \mathbb{R}^{N \times N} \) that satisfies the above conditions is a hyperbolic Gramian for a set of \( N \) points in \( \mathbb{L}^d \).

The proof is given in Proposition [3].
3.1 Solving for the H-Gramians

While Problem 1 could be formalized directly in $X$ domain, this approach is unfavorable as the optimization domain, $L^d$, is a non-convex set. What is more, the hyperbolic distances

$$d(x_m, x_n) = \text{acosh} \left(-e_m^T H X e_n\right)$$

are non-linear functions of $X$ with an unbounded gradient [25]. Similar issues arise when computing embeddings in other spaces such as Euclidean [14] or the space of polynomial trajectories [37]. A particularly effective strategy in the Euclidean case is the semidefinite relaxation which relies on the simple fact that the Euclidean Gramian is positive semidefinite. We thus proceed by formulating a semidefinite relaxation for hyperbolic embeddings based on Proposition 1.

Solving the HDGP involves two steps, summarized in Algorithm 1:

1. Complete and denoise the HDM via a semidefinite program;
2. Compute an embedding of the clean HDM: we propose a closed-form spectral factorization method.

Note that step (2) is independent of step (1): given accurate hyperbolic distances, spectral factorization will give the points that reproduce them. However, since the semidefinite relaxation might give a Gramian with a higher rank than desired, eigenvalue thresholding in step (2) might move the points off of $L^d$. That is because eigenvalue thresholding can violate the necessary condition for the hyperbolic norm, $\|x\|_H^2 = -1$, or $\text{diag} G = -1$ in Proposition 1. We fix this by projecting each individual point to $L^d$. The spectral factorization and the projection are summarized in Algorithms 2 and 3.

Algorithm 1 HDGP algorithm

1: procedure HDGP($\tilde{D}, \tilde{O}, d$)  
2: Input: Incomplete and noisy distance matrix, $\tilde{D}$, and ordinal measurements, $\tilde{O}$, and embedding dimension, $d$.  
3: $G = SDR(\tilde{D}, \tilde{O}, d)$ \quad $\triangleright$ Complete & denoise HDM.  
4: $X = \text{Embed}(G, d)$ \quad $\triangleright$ Embed points in $L^d$.  
5: For $X = [x_1, \ldots, x_N] \in (L^d)^N$, let $y_n = h(x_n), \forall n \in [N]$ where $h(\cdot)$ is given by (6). \quad $\triangleright$ Map the points to $I^d$.  
6: return $Y = [y_1, \cdots, y_N] \in (I^d)^N$.  
7: end procedure

Let $\tilde{D}$ be the measured noisy and incomplete HDM, with unknown entries replaced by zeroes. We define the mask matrix $W = (w_{ij})$ as

$$w_{ij} \overset{\text{def}}{=} \begin{cases} 1, & \text{for } (i,j) \in \mathcal{C} \lor (j,i) \in \mathcal{C} \\ 0, & \text{otherwise.} \end{cases}$$

This mask matrix lets us compute the loss only at those entries that were actually measured. We use the semidefinite characterization of hyperbolic Gramians in Proposition 1 to complete and denoise the measured HDM, and eventually solve HDGP.

Let \( \tilde{D} \) be the measured noisy and incomplete HDM, with unknown entries replaced by zeroes. We define the mask matrix $W = (w_{ij})$ as

$$w_{ij} \overset{\text{def}}{=} \begin{cases} 1, & \text{for } (i,j) \in \mathcal{C} \lor (j,i) \in \mathcal{C} \\ 0, & \text{otherwise.} \end{cases}$$

This mask matrix lets us compute the loss only at those entries that were actually measured. We use the semidefinite characterization of hyperbolic Gramians in Proposition 1 to complete and denoise the measured HDM, and eventually solve HDGP.
Table 3: Examples of specialized HDGP objectives.

| Cost function | Parameters | Applications |
|---------------|------------|--------------|
| $\text{Tr } W_k^+ G^+ + \text{Tr } W_k^- G^-$ | $W_k^+ = I, W_k^- = I$ | Low-rank hyperbolic embedding [15] [20] [21] |
| $\text{Tr } G^+ + \text{Tr } G^- + \sum_k p_k\epsilon_k$ | $p_k = 1$ | Ordinal outlier removal [12] [23] [13] |
| $\text{Tr } G^+ + \lambda \| G \|_{1,2} + \text{Tr } W_k^+ G^+ + \text{Tr } W_k^- G^-$ | $\| \cosh[\tilde{D}] + G^+ - G^- + C \|_F \leq \epsilon$ | Anomaly detection in weighted graphs [26] |

Although the set of hyperbolic Gramians for a given embedding dimension is non-convex due to the rank constraints, discarding the rank constraints results in a straightforward semidefinite relaxation. However, if we convexify the problem by simply discarding the rank constraints, then

Algorithm 2 Semidefinite relaxation for HDGP

1: **procedure** SDR($\tilde{D}, \tilde{O}, d$)
2: **Input:** Incomplete and noisy distance matrix, $\tilde{D}$, and ordinal measurements, $\tilde{O}$, and embedding dimension, $d$.
3: Let $W$ be the measurement mask.
4: For small $\epsilon_1, \epsilon_2 > 0$, solve for $G$:
   
   minimize $\text{Tr } G^+ + \text{Tr } G^-$
   
   w.r.t $G^+, G^- \succeq 0$

   subject to $G = G^+ - G^-$,
   
   $\text{diag } G = -1$,
   
   $\epsilon_i^T Ge_j \leq -1$, $\forall i, j \in [N]$,
   
   $\| W \circ (\cosh[\tilde{D}] + G) \|_F \leq \epsilon_1$,
   
   $L_k(G) \geq \epsilon_2$, $\forall k \in \tilde{O}$.

5: **return** $G$.
6: **end procedure**

all pairs $(G_1, G_2) \in \{(G^+ + P, G^- + P) : P \succeq 0\}$ become a valid solution. On the other hand, since $\text{rank } G + P \geq \text{rank } G$ for $G, P \succeq 0$, we can eliminate this ambiguity by promoting low-rank solutions for $G^+$ and $G^-$. While directly minimizing $\text{rank } G^+ + \text{rank } G^-$ (10) is NP-hard [27], there exist many approaches to make it computationally tractable, such as trace norm minimization [28], iteratively reweighted least squares minimization [10], or the log-det heuristic [41] that minimizes the following smooth surrogate for (10):

$$\log \det (G^+ + \delta I) + \log \det (G^- + \delta I),$$

where $\delta > 0$ is a small regularization constant. This objective function is linearized as

$$C + \text{Tr } W_k^+ G^+ + \text{Tr } W_k^- G^-,$$
for $W_k^+ = (G_k^+ + \delta I)^{-1}$ and $W_k^- = (G_k^- + \delta I)^{-1}$, which can be iteratively minimized. In our numerical experiments we will use the trace norm minimization unless otherwise stated. Then, we enforce the data fidelity objectives and the properties of the embeddings space (Proposition 1) in the form of a variety of constraints:

- **Metric embedding**: The quadratic constraint
  \[
  \left\| W \circ (\cosh[\mathcal{D}] + G) \right\|_F^2 \leq \epsilon_1
  \]
  makes sure the hyperbolic Gramian, $G$, accurately reproduces the given distance data.

- **Non-metric embedding**: The ordinal measurement constraint of
  \[
  d(x_{i_1}, x_{i_2}) \leq d(x_{i_3}, x_{i_4}),
  \]
  is simply a linear constraint in form of
  \[
  \mathcal{L}_i(G) = e_{i_1}^T G e_{i_2} - e_{i_3}^T G e_{i_4} \geq 0
  \]
  where $i \in \mathcal{O}$ and $i = (i_1, i_2, i_3, i_4)$. In practice, we replace this constraint by $\mathcal{L}_i(G) \geq \epsilon_2 > 0$ to avoid trivial solutions.

- **'Loid model**: The unit hyperbolic norm appears as a simple linear constraint
  \[
  \text{diag } G = -1,
  \]
  which guarantees that the embedded points reside in sheets $L^d \cup -L^d$. Finally, $e_i^T G e_j \leq -1$ enforces all embedded points to belong to the same hyperbolic sheet, i.e. $x_n \in L^d$ for all $n \in [N]$.

This framework can serve as a bedrock for multitude of other data fidelity objectives. We can seamlessly incorporate outlier removal schemes by introducing slack variables into the objective function and constraints. For example, the modified objective function
\[
\text{Tr } G^+ + \text{Tr } G^- + \sum_k \epsilon_k
\]
can be minimized subject to $\mathcal{L}_k(G) + \epsilon_k \geq 0$ and $\epsilon_k \geq 0$ as a means of removing outlier comparisons (we allow some comparisons to be violated; see Section 4.3 for an example).

We can similarly implement outlier detection in metric embedding problems. As an example, we can adapt the outlier pursuit algorithm. Consider the measured $H$-Gramian of a point set with a few outliers
\[
\hat{G} = G + C + N
\]
where $G$ is outlier-free hyperbolic Gramian, $C$ is a matrix with only few non-zero columns and $N$ represents the measurement noise. Outlier pursuit aims to minimize a convex surrogate for
\[
\text{rank } G + \lambda \left\| C \right\|_{0,c} \text{ s.t. } \left\| \hat{G} - G - C \right\|_F^2 \leq \epsilon
\]
where $\left\| C \right\|_{0,c}$ is the number of non-zero columns of $C$; more details and options are given in Table 3.

\[\text{In practice, we choose a diminishing sequence of } \delta_k.\]
3.2 Low-rank Approximation of H-Gramians

From Proposition 1, it is clear that the rank of a hyperbolic Gramian of points in \( \mathbb{L}^d \) is at most \( d + 1 \). However, the H-Gramian estimated by the semidefinite relaxation in Algorithm 2 does not necessarily have the correct rank. Therefore, we want to find its best rank-(\( d + 1 \)) approximation, namely \( \hat{G} \), such that

\[
\| G - \hat{G} \|_F^2 = \inf_{X \in (\mathbb{L}^d)^N} \| G - X^\top H X \|_F^2.
\] (11)

In Algorithm Algorithm 3, we propose a simple but suboptimal procedure to solve this low-rank approximation problem. Unlike iterative refinement algorithms based on optimization on manifolds \[38\] our proposed method is one-shot. It is based on the spectral factorization of the estimated hyperbolic Gramian and involves the following steps:

- **Step 1:** We find a set of points \( \{ z_n \} \) in \( \mathbb{R}^{d+1} \), whose Lorentz Gramian best approximates \( G \); See Definition 3 and lines 2 to 5 of Algorithm 3. In other words, we relax the optimization domain of (11) from \( \mathbb{L}^d \) to \( \mathbb{R}^{d+1} \),

\[
Z = \arg \min_{X \in \mathbb{R}^{(d+1) \times N}} \| G - X^\top H X \|_F^2.
\]

- **Step 2:** We project each point \( z_n \) onto \( \mathbb{L}^d \), i.e.

\[
\hat{X} = \arg \min_{X \in (\mathbb{L}^d)^N} \| X - Z \|_F^2.
\]

This gives us an approximate rank-(\( d + 1 \)) hyperbolic Gramian, \( \hat{G} = \hat{X}^\top H \hat{X} \); see Figure 2 and Section 6.3.

**Algorithm 3** Low-rank approximation and spectral factorization of hyperbolic Gramian

\begin{algorithm}
\begin{enumerate}
\item **procedure** Embed\((G, d)\)\n\item **Input:** Hyperbolic Gramian \( G \), and embedding dimension \( d \).
\item Let \( U^\top \Lambda U \) be eigenvalue decomposition of \( G \), where \( \Lambda = \text{diag} (\lambda_0, \cdots, \lambda_{N-1}) \) such that
  \begin{itemize}
  \item \( \lambda_0 = \min_i \lambda_i \),
  \item \( \lambda_i \) is the top \( i \)-th element of \( \{ \lambda_i \} \) for \( i \in [N] - 1 \).
  \end{itemize}
\item Let \( G_{d+1} = U^\top_d \Lambda_d U_d \), where
  \[
  \Lambda_d = \text{diag} (\lambda_0, u(\lambda_1), \cdots, u(\lambda_d)),
  \]
  \( u(x) = \max \{ x, 0 \} \), and \( U_d \) be the corresponding sliced eigenvalue matrix.
\item \( Z = R[\Lambda_d]^{1/2} U_d^\top \), for any H-unitary matrix \( R \).
\item For \( Z = [z_1, \ldots, z_N] \), let \( x_n = \text{Project}(z_n), \forall n \in [N] \)
\item **return** \( X = [x_1, \ldots, x_N] \in (\mathbb{L}^d)^N \).
\item **end procedure**
\end{enumerate}
\end{algorithm}

The first step of low-rank approximation of a hyperbolic Gramian \( G \) can be interpreted as finding the positions of points in \( \mathbb{R}^{d+1} \) (not necessarily on \( \mathbb{L}^d \)) whose Lorentz Gramian best approximates \( G \).
3.3 Spectral Factorization of H-Gramians

To finally compute the point locations, we derive a spectral factorization method to estimate point positions from their Lorentz Gramian (line 5 of Algorithm 3). This method exploits the fact that Lorentz Gramians have only one non-positive eigenvalue (see Lemma 1 in the appendix) as detailed in the following proposition.

Proposition 2. Let $G$ be a hyperbolic Gramian for $X \in (L^d)^N$, with eigenvalue decomposition $G = U \Lambda U^T$, and eigenvalues $\lambda_0 \leq 0 \leq \lambda_1 \leq \ldots \leq \lambda_d$. Then, there exists an $H$-unitary matrix $R$ such that $X = R|\Lambda|^{1/2}U$.

The proof is given in Section 6.2. Note that regardless of the choice of $R$, $X = R|\Lambda|^{1/2}U$ will reproduce $G$ and thus the corresponding distances. This is the rigid motion ambiguity familiar from the Euclidean case [33]. If we start with an $H$-Gramian with a wrong rank, we need to follow the spectral factorization by Step 2 where we project each point $z_n \in \mathbb{R}^{d+1}$ onto $L^d$. This heuristic is suboptimal, but it is nevertheless appealing since it only requires a single one-shot calculation as detailed in Section 6.3.

4 Experimental Results

In this section we numerically demonstrate different properties of Algorithm 1 in solving HDGPs. In a general hyperbolic embedding problem, we have a mix of metric and non-metric distance measurements which can be noisy and incomplete.

4.1 Missing Measurements

Missing measurements are a common problem in hyperbolic embeddings of concept hierarchies. For example, hyperbolic embeddings of words based on Hearst-like patterns rely on co-occurrence probabilities of word pairs in a corpus such as WordNet [50]. These patterns are sparse since word pairs must be detected in the right configuration [7]. In perceptual embedding problems, we ask...

---

3 An H-Gramian is a Lorentz Gramian.
individuals to rate pairwise similarities for a set of objects. It may be difficult to collect and embed all pairwise comparisons in applications with large number of objects \[31\]. The proposed semidefinite relaxation gives a simple way to handle missing measurements. The metric sampling density \(0 \leq S \leq 1\) of a measured HDM is the ratio of the number of missing measurements to total number of pairwise distances, \(S = 1 - \frac{|D|}{|D_c|}\). We want to find the probability \(p(S)\) of successful estimation given a sampling density \(S\). In practice, we fix the embedding dimension, \(d\), and the number of points, \(N\), and randomly generate a point set, \(X \in (L^d)^N\). A trial is successful if we can solve the HDGP for noise-free measurements and a random mask \(W\) of a fixed size so that the estimated hyperbolic Gramian has a small relative error, \(e_{rel}(\hat{G}) = \frac{\|D(X) - \text{acosh}[\hat{G}]\|_F}{\|D(X)\|_F} \leq \delta\).

We repeat for \(M\) trials, and empirically estimate the success probability as \(\hat{p}(S) = \frac{M_s}{M}\) where \(M_s\) is the number of successful trials. We repeat the experiment for different values of \(N\) and \(d\), see Figure 3.

For non-metric embedding applications, we want to have consistent embedding for missing ordinal measurements. The ordinal sampling density \(0 \leq S \leq 1\) of a randomly selected set of ordinal measurements is defined as \(S = 1 - \frac{|O|}{|O_c|}\). For a point set \(X \in (L^d)^N\), we define the average relative error of estimated HDMs, as follows \(e_{rel}(X) = \mathbb{E}_M \frac{\|D_O - \mathbb{E}_M[D_O]\|_F}{\|\mathbb{E}_M[D_O]\|_F}\) where \(D_O\) is the estimated HDM for ordinal measurements \(O\), and empirical expectation is with respect to the random ordinal set \(O\). We repeat the experiment for \(K\) different realizations of \(X \in (L^d)^N\) (Figure 3). We can observe that across different embedding dimensions, the maximum allowed fraction of missing measurements for a consistent and accurate estimation increases with the number of points.

### 4.2 Weighted Tree Embedding

Tree-like hierarchical data occurs commonly in natural scenarios. In this section, we want to compare the embedding quality of weighted trees in hyperbolic and the baseline in Euclidean space.

We generate a random tree \(T\) with \(N\) nodes, maximum degree of \(\Delta(T) = 3\), and i.i.d. edge weights from \(\text{unif}(0, 1)\). Let \(D_T\) be the distance matrix for \(T\), where the distance between each two

\[4\text{The most likely maximum degree for trees with } N \leq 25 \[31\].]
nodes is defined as the weight of the path joining them.

For the hyperbolic embedding, we apply Algorithm 2 with log-det heuristic objective function to acquire a low-rank embedding. On the other hand, Euclidean embedding of $T$ is the solution to the following semidefinite relaxation

$$
\begin{align*}
\text{minimize} & \quad \|D_T^{2} - K(G)\|_F^2 \\
\text{w.r.t} & \quad G \succeq 0 \\
\text{subject to} & \quad G1 = 0
\end{align*}
$$

where $K(G) = -2G + \text{diag}(G)1^T + 1\text{diag}(G)^T$, and $D_T^{2}$ is the entrywise square of $D_T$. This SDR yields a minimum error embedding of $T$, since the embedded points can reside in an arbitrary dimensional Euclidean space.

The embedding methods based on semidefinite relaxation are generally accompanied by a projection step to account for the potentially incorrect embedding dimension. For hyperbolic embedding problems, this step is summarized in Algorithm 3 whereas it is simply a singular value thresholding of the Gramian for Euclidean problems. Note that the SDRs always find a $(N-1)$-dimensional embedding for a set of $N$ points; see Algorithm 2 and (12). In this experiment, we define the optimal embedding dimension as

$$
d_0 = \min \left\{ d \in \mathbb{N} : \frac{\|D_{N-1} - D_d\|_F}{\|D_{N-1} - D_{d+1}\|_F} \geq 1 - \delta \right\}
$$

where $D_n$ is the distance matrix for embedded points in $\mathbb{L}^n$ (or $\mathbb{R}^n$), and $\delta = 10^{-3}$. This way, we accurately represent the estimated distance matrix in a low dimensional space. Finally, we define

Figure 4: Tree embedding in hyperbolic (red) and Euclidean (green) space. Discrete distribution of optimal embedding dimension for $M = 100$, (a) and (b). Average, $E_M[e_{rel}(T)]$, and standard deviation of embedding error, (c) and (d).
the relative (or normalized) error of embedding $T$ in $d_T$-dimensional space as

$$e_{rel}(T) = \frac{\|D_T - D_0\|_F}{\|D_T\|_F}.$$  

We repeat the experiment for $M$ randomly generated trees $T$ with a varying number of vertices $N$. The hyperbolic embedding yields smaller average relative embedding error $E_M[e_{rel}(T)]$ compared to Euclidean embedding, see Figure 4. It should also noted that the hyperbolic embedding has a lower optimal embedding dimension, even though the low-rank hyperbolic Gramian approximation is sub-optimal.

### 4.3 Odor Embedding

In this section, we want to compare hyperbolic and Euclidean non-metric embeddings of olfactory data following the work of Zhou et al. [23]. We conduct identical experiments in each space, and compare embedding quality of points from Algorithm 2 in hyperbolic space to its semidefinite relaxation counterpart in Euclidean space, namely generalized non-metric MDS [31].

We use an olfactory dataset comprising mono-molecular odor concentrations measured from blueberries [52]. In this dataset, there are $N = 52$ odors across the total of $M = 164$ fruit samples. Like Zhou et al. [23], we begin by computing correlations between odor concentrations across samples [23]. The correlation coefficient between two odors $x_i$ and $x_j$ is defined as

$$C(i, j) = \frac{(x_i - \mu_{x_i})\top(x_j - \mu_{x_j})}{\|x_i - \mu_{x_i}\| \|x_j - \mu_{x_j}\|}$$

where $x_n = (x_n^{(1)}, \ldots, x_n^{(M)})^\top$, $x_i^{(m)}$ is the concentration of $i$-th odor in $m$-th fruit sample, $M$ is total number of fruit samples and $\mu_{x_n} = \frac{1}{M} \sum_{m=1}^M x_n^{(m)}$.

The goal is to find an embedding for odors $y_1, \ldots, y_N \in \mathbb{R}^d$ such that

$$d(y_{i_1}, y_{i_2}) \leq d(y_{i_3}, y_{i_4}), \quad (i_1, i_2, i_3, i_4) \in \mathcal{O},$$

where,

$$\mathcal{O} = \mathcal{O}_c = \left\{(i_1, i_2, i_3, i_4) \in \left([N]_3^{2}\right)^2 : C(i_1, i_2) \geq C(i_3, i_4)\right\}.$$  

The total number of distinct comparisons grows rapidly with the number of points, namely $|\mathcal{O}_c| = 0.87$ million. In this experiment, we choose a random set of size $|\mathcal{O}| = 2K\binom{N}{2}$ for $K = 4$ to have the sampling density of $S = 98.79\%$ which brings the size of ordinal measurements to $|\mathcal{O}| \approx 10^4$.

We ensure the embedded points do not collapse by imposing the following minimum distance constraint $d(x_i, x_j) \geq 1$ for all $(i, j) \in [N]_3^2$: this corresponds to a simple linear constraint in the proposed formulation. An ideal order embedding accurately reconstructs the missing comparisons. We calculate the percentage of correctly reconstructed distance comparisons as

$$\gamma_d = |\hat{\mathcal{O}}_{c,d} \cap \mathcal{O}_{c}|/|\mathcal{O}_{c}|,$$

where $\hat{\mathcal{O}}_{c,d}$ is the complete ordinal set corresponding to a $d$-dimensional embedding.

A simple regularization technique helps to remove outlier measurements and improve the generalized accuracy of embedding algorithms. We introduce the parameter $\zeta_p$ to permit SDR algorithms to dismiss at most $p$-percent of measurements, namely

$$L_k(G) + \epsilon_k \geq \epsilon_2 \text{ and } \epsilon_k \geq 0, \quad \forall k \in \mathcal{O} \text{ and } \sum_{k} \epsilon_k \leq \zeta_p$$

where $\zeta_p$ is the ratio of number of ordinal measurements to number of variables, i.e. $K = \frac{|\mathcal{O}|}{2}\binom{N}{2}$. 

In hyperbolic embedding, this is the ratio of number of ordinal measurements to number of variables, i.e. $K = \frac{|\mathcal{O}|}{2}\binom{N}{2}$. 

15
where $\zeta_p = \frac{p}{n} |O| e_2$.

In Figure 5, we show the embedded points in $\mathbb{I}^2$ and $\mathbb{R}^2$ with different levels of allowable violated measurements. We can observe in Table 4 that hyperbolic space better represents the structure of olfactory data compared to Euclidean space of the same dimension. This is despite the fact that the number of measurements per variable is in favor of Euclidean embedding, and that the low rank approximation of hyperbolic Gramians is suboptimal. Moreover, if we remove a small number of outliers we can produce more accurate embeddings. These results corroborate the statistical analysis of Zhou et al. [23] that aims to identify the geometry of the olfactory space.

Table 4: Hyperbolic versus Euclidean embedding: reconstruction accuracy of ordinal measurements $\gamma_d$ for different levels of allowable violated measurements $\zeta_p$.

| Space    | $d = 2$ | $d = 4$ | $d = 6$ | $d = 8$ | $d = 10$ |
|----------|---------|---------|---------|---------|----------|
| Hyperbolic | $\zeta_0$ | 76.06  | 83.60  | 86.87  | 89.48  | 91.03   |
|          | $\zeta_{0.5}$ | 76.52  | 83.71  | 86.94  | 89.68  | 91.16   |
|          | $\zeta_1$   | 76.43  | 83.71  | 86.92  | 89.76  | 91.21   |
| Euclidean | $\zeta_0$   | 73.44  | 78.86  | 82.23  | 85.06  | 88.67   |
|          | $\zeta_{0.5}$ | 73.27  | 79.03  | 82.65  | 86.24  | 88.98   |
|          | $\zeta_1$   | 73.12  | 78.92  | 82.51  | 86.01  | 89.02   |

---

6 Statistical analysis of Betti curve behavior of underlying clique topology [36]
5 Conclusion

We introduced hyperbolic distance matrices, an analogy to Euclidean distance matrices, to encode pairwise distances in the 'Loid model of hyperbolic geometry. Same as in the Euclidean case, although the definition of hyperbolic distance matrices is trivial, analysing their properties gives rise to powerful algorithms based on semidefinite programming. We proposed a semidefinite relaxation which is essentially plug-and-play: it easily handles a variety of metric and non-metric constraints, outlier removal, and missing information and can serve as a template for different applications. Finally, we proposed a closed-form spectral factorization algorithm to estimate the point position from hyperbolic Gramians. Several important questions are still left open, most notably the role of the isometries in the 'Loid model and the related concepts such as Procrustes analysis.

Reproducible Research

The research described in this paper is completely reproducible. The experimental code is written in Python with the help of the cvxpy environment [53]. Code and data and documentation to reproduce the experimental results are available at https://github.com/swing-research/hdm.

Acknowledgement

We would like to thank Lav Varshney for bringing our attention to hyperbolic geometry and for critical reading and comments on the manuscript.

6 Appendices

6.1 Proof of Proposition 1

A hyperbolic Gramian can be written as $G = X^T H X$ for a $X = [x_1, \ldots, x_N] \in (L^d)^N$. Let us rewrite it as

$$G = \sum_{i=1}^{d} g_i g_i^T - g_0 g_0^T = G^+ - G^-$$

where $g_i^T$ is the $(i+1)$-th row of $X$, $G^- = g_0 g_0^T$ and $G^+ = \sum_{i=1}^{d} g_i g_i^T$ are positive semidefinite matrices. We have rank $G^- \leq 1$ and rank $G^+ \leq d$. On the other hand, we have

$$e_i^T Ge_j \overset{\text{def}}{=} [x_i, x_j] = -x_{0,i}x_{0,j} + \sum_{k=1}^{d} x_{k,i}x_{k,j} \leq -(1 + \bar{x}_i^T \bar{x}_j) + \bar{x}_i^T \bar{x}_j = -1.$$
where \( x_{k,i} \) is the \((k+1)\)-th element of \( x_i, \bar{x}_i = (x_{1,i}, \ldots, x_{d,i})^\top \), and (a) is due to \( \|x_i\|_H^2 = \|x_j\|_H^2 = -1 \), and (b) results from Cauchy-Shwartz inequality. The equality holds for \( i = j \), which yields the diag \( G = -1 \) condition.

Conversely, let \( G = G^+ - G^- \), where \( G^+, G^- \geq 0 \), rank \( G^- \leq 1 \), and rank \( G^+ \leq d \). Let us write \( G^- = g_0 g_0^\top \) and \( G^+ = \sum_{i=1}^d g_i g_i^\top \) for \( g_0, \ldots, g_d \in \mathbb{R}^N \). Then, we define

\[
X \overset{\text{def}}{=} \begin{bmatrix}
g_0^\top \\
\vdots \\
g_d^\top
\end{bmatrix} = [x_1, \ldots, x_N] \in \mathbb{R}^{(d+1) \times N}.
\]

where \( x_n \in \mathbb{R}^{d+1} \) for all \( n \in [N] \). By construction, we have \( X^\top H X = G \), and

\[
\text{diag } G = -1 \Rightarrow \|x_n\|_H^2 = -1, \quad \forall n \in [N].
\]

Finally, \( e_i^\top G e_j \leq -1 \) guarantees that \( x_n \in \mathbb{L}^d \) for all \( n \in [N] \). We prove the contrapositive statement. Let \( x_i \) and \( x_j \) belong to different the hyperbolic sheets, e.g. \( x_i \in \mathbb{L}^d, x_j \in -\mathbb{L}^d \). Then,

\[
e_i^\top G e_j \overset{\text{def}}{=} [x_i, x_j] = -x_{0,i}x_{0,j} + \sum_{k=1}^d x_{k,i}x_{k,j}
\]

\[
\geq \sqrt{1 + \|x_i\|^2} \sqrt{1 + \|x_j\|^2} - \|x_i\| \|x_j\| \geq 0
\]

where (a) is due to Cauchy-Shwartz inequality. This is in contradiction with \( e_i^\top G e_j \leq -1 \) condition. Therefore, \( \{x_n\} \) belong to the same hyperbolic sheet, namely \( \mathbb{L}^d \).

6.2 Derivations for Algorithm 3

Theorem 1. Let \( G \in \mathbb{R}^{N \times N} \) be a hyperbolic Gramian, with eigenvalue decomposition

\[
G = U^\top \Lambda U,
\]

where \( \Lambda = \text{diag}(\lambda_0, \cdots, \lambda_{N-1}) \) such that

- \( \lambda_0 = \min_i \lambda_i \),
- \( \lambda_i \) is the \(i\)-th top element of \( \{\lambda_i\} \) for \( i \in \{1, \cdots, d\} \)

The best rank-\((d+1)\) Lorentz Gramian approximation of \( G \), in \( \ell^2 \) sense, is given by

\[
G_{d+1} = U_d^\top \Lambda_d U_d
\]

where \( \Lambda_d = \text{diag}[\lambda_0, u(\lambda_1), \cdots, u(\lambda_d)], \ u(x) = \max\{x, 0\}, \) and \( U_d \in \mathbb{R}^{(d+1) \times N} \) is the corresponding sliced eigenvalue matrix.

Proof. We begin by characterizing the eigenvalues of a Lorentz Gramian.

Lemma 1. Let \( G \in \mathbb{R}^{N \times N} \) be a Lorentz Gramian of rank \( d + 1 \) with eigenvalues \( \psi_0 \leq \cdots \leq \psi_d \). Then, \( \psi_0 < 0 \), and \( \psi_i > 0 \), for \( i \in \{1, \cdots, d\} \).
Proof. We write Lorentzian Gramian, $G = (g_{i,j})$, as $G = X^\top HX$ where

$$X = [x_1, \cdots, x_N] = \begin{bmatrix} g_0^\top \\ \vdots \\ g_d^\top \end{bmatrix} \in \mathbb{R}^{(d+1) \times N}.$$ 

Then, $G = G^+ - G^-$ where $G^+ \overset{\text{def}}{=} \sum_{i=1}^{d} g_i g_i^\top$ is a positive semi-definite matrix of rank $d$ and with eigenvalues $0 < \gamma_1 \leq \cdots \leq \gamma_d$, and $-G^- \overset{\text{def}}{=} -g_0 g_0^\top$ is a negative definite matrix of rank 1, with eigenvalue $\mu \leq 0$. From Weyl’s inequality [54], we have

$$\mu + \gamma_1 \leq \psi_0 \leq \mu + \gamma_d$$

where $\psi_0$ is the smallest eigenvalue of $G$. Therefore, $\psi_0$ can be non-positive (negative if $\mu + \gamma_d < 0$). For other eigenvalues of $G$, we have

$$0 + \gamma_i \leq \psi_i \leq \gamma_d,$$

for $1 \leq i \leq d$. Hence, $\psi_i > 0$ for $i \in \{1, \cdots, d\}$. This is result is irrespective to the order of eigenvalues.

Now, let us prove $\psi_0 < 0$. Suppose $g_0 \in S = \text{span} \{g_i : i \in \{1, \cdots, d\}\}$. Then,

$$\text{rank} \, G = \text{rank} \begin{bmatrix} g_0^\top \\ \vdots \\ g_d^\top \end{bmatrix} < d + 1,$$

which is a contradiction. Therefore, we write $g_0 = \alpha t + \beta s$ where $s \in S$, $t \in S^\perp$ with $\|t\| = 1$, $\alpha, \beta \in \mathbb{R}$ and $\alpha \neq 0$. Then, we have

$$\psi_0 \leq t^\top G t \overset{(a)}{=} -t^\top g_0 g_0^\top t = -\alpha^2 < 0$$

where (a) is due to $G = -g_0 g_0^\top + \sum_{i=1}^{d} g_i g_i^\top$ and $t \in S^\perp$. \hfill \Box

Consider eigenvalue decomposition of $G$ in eq. (13). Without loss of generality, we assume

- $\lambda_0 = \min_i \lambda_i < 0$,
- $\lambda_i$ is the $i$-th top element of $\{\lambda_i\}$ for $i \in \{1, \cdots, d\}$.

By construction $G = X^\top HX$ and from diag $G = -1$ condition, we have

$$\sum \lambda_i = -N.$$ 

Therefore, $\lambda_0 < 0$. From Lemma [1] one eigenvalue of a Lorentz Gramian is negative and the rest must be positive. Therefore, $\tilde{G} = U_d^\top \Lambda_d U_d$ with eigenvalues $\Lambda_d = \text{diag} \{\lambda_0, u(\lambda_1), \cdots, u(\lambda_d)\}$ and eigenvectors $U_d = [u_0, \cdots, u_d]$, is the best rank-$(d + 1)$ Lorentz Gramian approximation to $G$, i.e.

$$\left\| \tilde{G} - G \right\|_2^2 = \inf_{H. \text{ Lorentz Gram. of rank } \leq d+1} \|H - G\|_2^2.$$ 

\hfill \Box
Finally, a rank-$(d+1)$ Lorentz Gramian with eigenvalue decomposition
\[ G_{d+1} = U_d \Lambda_d U_d^T \]
can be decomposed as \( X = R|\Lambda|^{1/2} U_d^T \in \mathbb{R}^{(d+1)\times N} \) where \( R \) is an arbitrary H-unitary matrix and \( G_{d+1} = X^T H X \).

### 6.3 Project: \( \mathbb{R}^d \to \mathbb{L}^d \)

**Algorithm 4** Projection from \( \mathbb{R}^{d+1} \) to \( \mathbb{L}^d \)

1: procedure Project(\( x \))
2: For \( x \in \mathbb{R}^{d+1} \), let
3: \[
\hat{x} = \begin{cases} 
(1, 0^T)^T & x \in \{ (x_0, 0^T) : x_0 \leq 2 \}, \\
\left( \frac{1}{2} x_0, \hat{x}_1, \cdots, \hat{x}_d \right)^T & x \in \{ (x_0, 0^T) : x_0 > 2 \} \\
x(\lambda) & \text{otherwise and for } \lambda:
\end{cases}
\]
\[ \|x(\lambda)\|^2_H = -1. \]
\[ S = \left\{ (x_1, \cdots, x_d) : x_1^2 + \cdots + x_d^2 = -1 + \frac{1}{4} x_0^2 \right\}. \]
4: return \( \hat{x} \).
5: end procedure

**Proof.** Let us reformulate the following projection problem
\begin{equation} \label{eq:projection}
\hat{x} \in \arg \min_{y \in \mathbb{L}^d} \| y - x \|^2
\end{equation}
as unconstrained augmented Lagrangian minimization, i.e.
\[ L(y, \lambda) = \| y - x \|^2 + \lambda (y^T H y + 1). \]
The first order necessary condition for \( \hat{x} \) to be a (local) minimum of eq. \eqref{eq:projection} is
\begin{equation} \label{eq:necessary_condition}
(I + \lambda^* H) \hat{x} = x
\end{equation}
for a \( \lambda^* \in \mathbb{R} \) such that \( \hat{x} \in \mathbb{L}^d \).

- \( \lambda^* = -1 \): This happens when \( x = (x_0, 0^T)^T \) and \( x_0 \geq 2 \). Following from optimality condition of eq. \eqref{eq:necessary_condition} and \( \| \hat{x} \|^2_H = -1 \), we have \( \hat{x} = \left( \frac{1}{2} x_0, \hat{x}_1, \cdots, \hat{x}_d \right)^T \), where
\[ x_1^2 + \cdots + x_d^2 = -1 + \frac{1}{4} x_0^2. \]
Therefore, \( \hat{x} \) could be any point on a \((d-1)\)-dimensional sphere on \( \mathbb{L}^d \). For \( x = (x_0, 0^T)^T \) and \( x_0 \leq 2 \), we have \( \hat{x} = (1, 0^T)^T \).
\( \lambda^* = 1 \): This happens for \( x = (0, x_1, \cdots, x_d)^T \). From optimality condition of eq. \( \text{[15]} \), we have 
\[
\hat{x} = (\hat{x}_0, \frac{1}{2}x_1, \cdots, \frac{1}{2}x_d), \quad \hat{x}_0 = \frac{1}{2} \sqrt{x_1^2 + \cdots + x_d^2 + 4}.
\]

For non-degenerate cases of \( \lambda^* \neq \pm 1 \), we have 
\[
\hat{x} = (I + \lambda^*H)^{-1}x,
\]
where \( \lambda^* \in \left\{ \lambda : \|(I + \lambda H)^{-1}x\|_H^2 = -1, \hat{x}_0 \geq 0 \right\} \).

(1) \( \lambda^* \in (-1, 1) \): First, we define
\[
f(\lambda) = \|(I + \lambda H)^{-1}x\|_H^2.
\]
This is a monotonous function on \((-1, 1)\), with \( \lim_{\lambda \to 1^-} f(\lambda) = -\infty \), and \( \lim_{\lambda \to 1^+} f(\lambda) = +\infty \).
Therefore, \( f(\lambda) = -1 \) has a unique solution \( \lambda^* \in (-1, 1) \). Finally, \( \hat{x} \) is a local minima since the second order sufficient condition
\[
I + \lambda^*H > 0
\]
is satisfied for \( \lambda^* \in (-1, 1) \). Lastly, from eq. \( \text{[16]} \), we have \( \hat{x}_0 \leq 0 \). In other words, \( \lambda^* \in [-1, 1] \) if and only if \( x \) is in the same half-space as \( L^d \), i.e. \( x_0 \geq 0 \).

(2) \( \lambda^* \in (-\infty, -1) \): Similarly, \( f(\lambda) \) is a continuous function in this interval with \( \lim_{\lambda \to -1^-} f(\lambda) = +\infty \), \( \lim_{\lambda \to -1^+} f(\lambda) = 0 \), and its first order derivative
\[
\frac{d}{d\lambda} f(\lambda) = -\frac{2}{(1-\lambda)^3} x_0^2 - \frac{2}{(1+\lambda)^3} \sum_{i=1}^{d} x_i^2
\]
has at most one zero. Therefore, \( f(\lambda) = -1 \) has at most two solutions. The second order necessary condition for local minima is \( v^\top (I + \lambda^*H)v \geq 0 \) for all \( v \in T_xL^d \), where
\[
T_xL^d = \left\{ v \in \mathbb{R}^{d+1} : x^\top (I + \lambda^*H)^{-1}Hv = 0 \right\}.
\]
However, there exists a \( v \in T_xL^d \) where \( v = (0, \bar{v}^\top)^T \) which violates the second order necessary condition, \( v^\top (I + \lambda^*H)v < 0 \). Therefore, \( \hat{x} \) even if it exists – is not a local minima.

(3) \( \lambda^* \in (1, \infty) \): We can easily see that \( \lim_{\lambda \to 1^-} f(\lambda) = -\infty \), \( \lim_{\lambda \to +\infty} f(\lambda) = 0 \), and \( \frac{d}{d\lambda} f(\lambda) = 0 \) has at most one solution in this interval. Therefore, \( f(\lambda) = -1 \) has exactly one solution. However, we have \( \hat{x}_0 \leq 0 \) from eq. \( \text{[16]} \). In other words, \( \lambda^* \in (1, \infty) \) if and only if \( x \) is in the opposite half-space of \( L^d \), i.e. \( x_0 \leq 0 \). Finally, \( \hat{x} \) is the unique minima, since the projection of \( x \notin S \) to the closed and convex set of
\[
S = \left\{ x : x_0 \geq 0, \|x\|_H^2 \leq -1 \right\}
\]
always exits and is unique.

\[\square\]
