In this paper we propose the most general classification of point-like and line-like extrinsic topological defects in (2+1)-dimensional Abelian topological states. We first map generic extrinsic defects to boundary defects, and then provide a classification of the latter. Based on this classification, the most generic point defects can be understood as domain walls between topologically distinct boundary regions. We show that topologically distinct boundaries can themselves be classified by certain maximal subgroups of mutually bosonic quasiparticles, called Lagrangian subgroups. We study the topological properties of the point defects, including their quantum dimension, localized zero modes, and projective braiding statistics.

A fundamental discovery in condensed matter physics has been the understanding of topologically ordered states of matter\cite{1, 2}. Topologically ordered states possess quasiparticle excitations with fractional statistics, long-range entanglement, all of which are robust even without symmetry. The most common topological orders seen experimentally are the fractional quantum Hall (FQH) states, while there is increasing evidence that they may also be observed in frustrated magnets\cite{3}.

Recently, a new aspect of topologically ordered states, called twist defects or extrinsic defects, has attracted increasing research interest.\cite{4-6} An extrinsic defect is a point-like or line-like defect either in a topological state, or on the interface between two topologically distinct states, which leads to topological properties that are absent without the defect. A simple example is a “genon”\cite{4, 5}. Consider a branch-cut line in a bilayer topological state, across which the two layers are exchanged (Fig. 1). A genon is defined as an end point of the branch cut. It was observed that the bilayer system with genons is topologically equivalent to a single layer system on a high genus surface, yielding a topological degeneracy that grows exponentially with the number of genons, and a notion of (projective) braiding statistics that can be studied systematically\cite{5}. Even when the topological state in each layer is Abelian, the genons have non-Abelian statistics. This has led to a recent experimental proposal for realizing a wide class of topological qubits in conventional bilayer FQH states\cite{8}, and an understanding of how to realize universal topological quantum computation in non-universal, non-Abelian states\cite{9}. Extrinsic defects with the same type of non-Abelian statistics as genons have also been proposed in other physical systems, such as lattice defects in certain exactly solvable $Z_N$ rotor models\cite{10}, and FQH states in proximity with superconductivity (SC) and ferromagnetism (FM).\cite{11-13, 17}

In this paper, we report a general theory of extrinsic defects in Abelian topological states, extending the theory of the extrinsic defects reviewed above to the most general possible form. For two-dimensional topological states, there are two general forms of extrinsic defects: \textit{Line defects}, which separate two different or identical topological states, and \textit{point defects}, which may exist in a single topological state, such as twist defects\cite{5}, or at junctions between different line defects (Fig. 2). We demonstrate that all extrinsic defects can be mapped to \textit{boundary defects}, i.e., boundary lines of topological states with point defects separating different boundary regions. Based on the understanding of boundary defects, we develop a classification of gapped line defects between Abelian topological states, extending previous results\cite{16, 18-23}. We prove that gapped line defects are classified by “Lagrangian subgroups,” which consist of subgroups of topological quasi-particles that have trivial self and mutual statistics, and that are condensed on the boundary.

The nontrivial point defects on the boundary are then classified by domain walls between topologically distinct line defects. We obtain the quantum dimension of general point defects, demonstrating that they are generally non-Abelian and can be understood in terms of the fractional statistics of bulk quasiparticle excitations. We show that the point defects localize a set of topologically protected zero modes, which can be understood as a localized, robust non-zero density of states at zero energy for a certain subgroup of the topological quasiparticles. Finally, we will briefly discuss the sense in which these non-Abelian boundary defects can be braided.

\textbf{Abelian topological states and line defects –} Abelian topological states in 2+1 dimensions are generically described by Abelian Chern-Simons (CS) theories\cite{1}.

\caption{(a) Schematic picture of bilayer system with a pair of genons.\cite{4, 5} (b) is the same figure as (a) with part of the system removed, to see the branch-cut line clearly.}
\end{figure}
Quasi-particles are labeled by integer vectors \( \theta \) given by 

\[
\theta = m \mathbf{l} \mod K \varepsilon
\]

with the number of topologically distinct quasiparticles calculated states if they have the same quasiparticle content.

Another example is 

\[
|l| \pi l
\]

with 

\[
\varepsilon = 1, \bar{\varepsilon} = -1
\]

Different K-matrices can specify equivalent topological states if they have the same quasiparticle content. For example, 

\[
K' = W^T K W
\]

with \( W \) an integer matrix with \( |\text{Det} W| = 1 \). Adding \( P \) does not introduce any new topological quasiparticles, so that \( K \) and \( K' \) describe the same topological order.

A general line defect in a topological state is a one-dimensional boundary between two topological states, \( A_1 \) and \( A_2 \) (see Fig. 2 (a)). Some line defects, such as the edge of chiral topological states, are robustly gapless. In this work we will explore gapped line defects.

In order to understand the properties of general boundaries, it is helpful to apply a folding process over, this can be mapped to a domain wall on the boundary separating \( A_1 \) and \( A_2 \) and the vacuum. (b) A junction where multiple gapped edges meet is also a possible type of point defect. On an infinite plane, by applying the folding trick multiple times, this can also be mapped to a domain wall on the boundary separating a topological phase and the vacuum.

Classification of gapped boundaries—The key feature of a gapped boundary of a topological phase is that some subgroup of the topological quasiparticles are condensed on the boundary, and can be created/annihilated on the boundary by local operators. Physically, this describes superselection sectors for how topological quasiparticles can be reflected/ transmitted at line defects. We first consider the genon case as an example.

Consider a simple bilayer topological state, the (mm0) Halperin state, with the \( K \) matrix \( K = m \mathbb{I}_{2 \times 2} \), which describes two independent 1/m-Laughlin FQH states. Here \( \mathbb{I}_{2 \times 2} \) is the 2-dimensional identity matrix. Folding the state along a line (see Fig. 3 (a)) we obtain a 4-layer system with the \( K \) matrix 

\[
K = \begin{pmatrix}
m \mathbb{I}_{2 \times 2} & 0 \\
0 & -m \mathbb{I}_{2 \times 2}
\end{pmatrix}
\]

The boundary of such a state can be gapped by introducing either interlayer or intralayer backscattering. The genon is defined as the domain wall between these two types of boundaries.

These two boundary conditions can be distinguished by the behavior of quasiparticles at the boundary. Across the boundary gapped by intralayer backscattering, quasiparticles move between layers 1, 2 and the vacuum. (b) A junction where multiple gapped edges meet is also a possible type of point defect. On an infinite plane, by applying the folding trick multiple times, this can also be mapped to a domain wall on the boundary separating a topological phase and the vacuum.

\[ e^{i\theta_{mm'}} = 1 \text{ for all } m, m' \in M; \]

2. For all \( l \notin M \), \( e^{i\theta_{lm}} \neq 1 \) for at least one \( m \in M \).
is completely gapped, since all other quasiparticles \( l \notin M \) have nontrivial mutual statistics with particles in \( M \), and thus are confined when the quasiparticles in \( M \) are condensed.

In the following we will strengthen this result by proving that every Lagrangian subgroup \( M \) corresponds to a gapped boundary where \( M \) is condensed.

To explicitly write down the boundary condition corresponding to a Lagrangian subgroup, we introduce the edge theory of the chiral Luttinger liquid theory [1, 24] of left- and right- moving modes, which is a necessary but not sufficient condition for the edge to be gapped.

The electron annihilation operators \( \Psi_I \) and quasiparticle annihilation operators \( \chi_I \) are given by \( \Psi_I = e^{i K_I \phi_I} \), \( \chi_I = e^{i \nu_I \phi_I} \), where \( I \) is an integer vector describing the quasiparticles. Naively, the condensation of a quasiparticle \( m \in M \) can be described by adding a term \( \frac{g}{2} (\chi_m + \chi_m^\dagger) = g \cos (m_1 \phi_I) \) to \( \mathcal{L}_{\text{edge}} \). However, such a term has two problems. First, it is not a local term, written in terms of local “electron” operators \( \Psi_I \). Second, the condition \( m^T K^{-1} m = 0 \) must be satisfied in order for the phase \( m_1 \phi_I \) to obtain a classical value. With this condition, the problem can be solved by multiplying an integer coefficient \( c_i \), such that \( c_i K^{-1} m_i \equiv \Lambda_i \in \mathbb{Z} \), and thus \( \cos (c_i m_1 \phi_I) = \cos (\Lambda_i^T K \phi) \) is a local electron tunneling operator.

The second can be solved if we can find a set of generators \( \{ m_i \} \) of \( M \) satisfying \( m_j^T K m_j = 0 \), \( \forall i, j \). Then, the term \( g \sum_i \cos (c_i m_i \phi_I) \) can be added to the Lagrangian and will condense the particles in \( M \): \( e^{i m^T \phi} \neq 0 \) if \( m \in M \). It is known that if one can find \( N \) such null vectors \( m_i \) for a \( 2N \times 2N \) \( M \) matrix, the edge can be completely gapped [22].

However, it is not always possible to find such a null vector basis \( \{ m_i \} \) which fully generates \( M \). For example, consider \( K = \begin{pmatrix} 0 & 4 \\ 4 & 0 \end{pmatrix} \), which describes \( \mathbb{Z}_4 \) topological order. This system has a Lagrangian subgroup generated by \( m_1^T = (2, 0), m_2^T = (0, 2) \). It is not possible to find a single null vector which generates this Lagrangian subgroup. Consequently, it is not clear what cos term on the boundary leads to the condensation of this Lagrangian subgroup.

This problem can be resolved by introducing a topologically equivalent \( K \) matrix with higher dimension, as is shown in Eq. [4]. In the edge theory, adding additional trivial blocks \( P \) such that \( P = \tau_x \) or \( \tau_z \), where \( \tau_i \) are \( 2 \times 2 \) Pauli matrices, corresponds to adding purely one-dimensional edge channels to the boundary, such as Heisenberg spin 1/2 chains. Thus we find:

**Lemma:** For each Lagrangian subgroup \( M \) of the topological state described by \( K \), there exists a \( K' \) which is topologically equivalent to \( K \) and has rank(\( K' \)) = 2N', such that the same Lagrangian subgroup \( M \) of \( K' \) can be generated by \( N' \) null vectors \( m_i' \), \( i = 1, 2, ..., N' \).

The proof of this conclusion will be presented in the appendix. As a simple example that illustrates the main idea of the proof, consider the previous example, with \( K = \begin{pmatrix} 0 & 4 \\ 4 & 0 \end{pmatrix} \), and \( m_1^T = (2, 0), m_2^T = (0, 2) \). We define \( K' = \begin{pmatrix} K & 0 \\ 0 & \tau_z \end{pmatrix} \), and \( m_1'^T = (2, 0, 0, 1), m_2'^T = (0, 2, -1, 0) \). Here, \( K' \) is topologically equivalent to \( K \), and \( m_i'^T K'^{-1} m_i' = 0 \). Physically, this result implies that one can always condense the particles in a Lagrangian subgroup on the edge, as long as using additional trivial edge states is allowed.

We conclude that every Lagrangian subgroup \( M \) corresponds to a gapped boundary where \( M \) is condensed, providing a classification, in the absence of any symmetries, of topologically distinct gapped boundaries.

**Classification and characterization of point defects**—In general, a point defect is a junction where multiple different line defects meet. Under the folding process, which may be applied multiple times, the point defects can always be mapped to domain walls between two gapped edges (Fig. 2). Therefore it is sufficient to study the point defect at the domain wall between two gapped boundaries. Based on the above classification of gapped boundaries, the domain walls are thus classified by a pair of Lagrangian subgroups \( (M, M') \), corresponding to the gapped boundaries on either side of the domain wall.

Consider a point defect labelled by \( (M, M') \). In the genon example reviewed above, the simplest topological property of the point defect is its nontrivial quantum dimension. This can be understood from the fact that the bilayer system (on the sphere) with \( 2n \) genons has genus \( n - 1 \), which leads to a topological ground state degeneracy that grows exponentially in \( n \). For Abelian states, the topological degeneracy can be obtained from the algebra of the Wilson loop operators, which measure the topological charge through non-contractible loops. For example, a sphere with 4 genons is equivalent to a torus, which has two non-contractible loops \( a, b \) (see Fig. 3(a)). When each layer is a 1/m Laughlin state, the Wilson loop operators \( W(a) \) and \( W(b) \) are defined by creating a pair of charge \( 1/m, -1/m \) particles and taking one of them around the loops \( a \) and \( b \), and then annihilating them. \( W(a)W(b) \) satisfies the commutation relation \( W(a)W(b) = W(b)W(a)e^{2\pi i/m} \), and each leave the system in its ground state subspace, requiring the ground state degeneracy to be an integer multiple of \( m \). [5].
These Wilson loop operators can be generalized to the generic point defects. By folding the bilayer system with genons along a line containing the genons, the Wilson loops become Wilson lines of the particles \((1/m, 0, -1/m, 0)\) or \((1/m, 0, 0, -1/m)\), which terminate at the boundary since the corresponding particles are condensed at the boundary. For general defects, between two gapped boundaries \(A, B\) with Lagrangian subgroups \(M\) and \(M'\), respectively, the Wilson lines can be defined (Fig. 3(b)) by creating a boson \(m \in M\) at the boundary using a local operator, moving it along a path \(a\) connecting two \(A\) regions, and finally annihilating it using a local operator. We denote such an operator as \(W_m(a)\) and similarly \(W_{m'}(b)\) for moving particle \(m' \in M'\) between two \(B\) regions. The commutation relation between \(W_m(a)\) and \(W_{m'}(b)\) is determined by the mutual statistics of particles \(m\) and \(m'\), which is nontrivial when \(M\) and \(M'\) are different Lagrangian subgroups:

\[
W_m(a)W_{m'}(b) = W_{m'}(b)W_m(a) e^{2 \pi i m^T K^{-1} m'}.
\]

Since these operators leave the system in the ground state subspace, the ground states must form a representation of this algebra.

The degeneracy \(D\) required by one pair of non-contractible intersecting lines \(a, b\) is the dimension of the minimal representation of the algebra \((2)\), which can be obtained by acting on the states \(\{W_m(a)\}\) and \(\{W_{m'}(b)\}\), respectively, with the unitary operator \(W_m(a) W_{m'}(b)\) which correspond to adiabatic motion of bosonic quasiparticle \(m(m')\) along the paths \((a, b)\), respectively.

Effective braiding of point-defects – In the systems with genons or more generic twist defects, the non-Abelian braid statistics of defects can be defined projectively \(2\), which enables topologically protected transformations on the degenerate ground states. The more general boundary defects studied here cannot always be braided in real space, since the defects are confined to the boundary line defects. However, it has been proposed \(3, 11, 12, 31, 32\) that effective braiding operators can be achieved by controlling the quasiparticle tunneling between point defects. The general defects we studied can be coupled by tunneling of the zero mode quasiparticles \(\gamma_l\) in Eq. (3). The tunneling Hamiltonian has the form \(H_{ab} = \sum_{l \in L} t_l \gamma_l^a(x_a) \gamma_l^b(x_b) + H.c.,\) where \(x_a\) and \(x_b\) are the positions of two equivalent defects, \(t_l\) is the tunneling amplitudes, and \(\gamma_l(x_a)\) are the zero mode operators at the defects. If \(H_{ab}\) has a unique ground state in the Hilbert space defined by the two defects \(a, b\), one can consider an adiabatic deformation of Hamiltonian \(H(\lambda) = H_{ab}(1 - \lambda) + H_\alpha \lambda\). When \(\lambda\) adiabatically changes from 0 to 1, the defect at \(c\) is transferred to \(a\). Combining such motions of defects, braiding between two defects can be realized. However, in order for \(H_{ab}\) to have a unique ground state in a Hilbert space defined by \(a, b\), we need the set \(L\) appearing in \(H_{ab}\) to consist only of quasiparticle...
cles of the form \( l_i = m_i + m'_i \), with the highly non-trivial requirement that \( m_i^2 K^{-1} m'_i = m_i^2 K^{-1} m'_i \), where \( \{ m_i \} \) (\( \{ m'_i \} \)) is a set of generators of the Lagrangian subgroup \( M (M') \). Otherwise we have not been able to define a notion of braiding. A general analysis of such braiding statistics for generic defects will be presented in later work [33].

Acknowledgement. We thank Alexei Kitaev for helpful discussions. After finishing this work, we learned that some of the results on the classification of line defects are independently found by Michael Levin and included in an updated version of Ref. [23]. We acknowledge support from the Simons foundation (MB) and Packard Foundation (XLQ).

Proof of Lemma

Here we prove the following lemma, which was presented in the main text:

Lemma: For each Lagrangian subgroup $M$ of the topological state described by $K$, there exists a $K'$ which is topologically equivalent to $K$ and has rank($K'$) = $2N'$, such that the same Lagrangian subgroup $M$ of $K'$ can be generated by $N'$ null vectors $m'_i$, $i = 1, 2, ..., N'$.

To prove this, we will focus on two cases independently. In the first case, $K$ has only even entries along the diagonals, which describes topological phases where the microscopic degrees of freedom only consist of bosons. In the second case, $K$ can have odd entries along the diagonals, which is appropriate when the microscopic degrees of freedom have at least one species of fermions.

We note that our Lemma and proof builds on results presented in an early version of Ref. [23]. As our paper was about to appear, we learned that the Lemma and proof presented here was independently also found by M. Levin and included in an updated version of Ref. [23].

Proof for $K$ even

Let us first consider the case where $K$ is an even matrix, meaning that its diagonal entries are all even. Note that $K$ is also an integer symmetric non-singular matrix with vanishing signature. Consider the lattice

$$\Gamma = \{ m + KA : m \in M, A \in \mathbb{Z}^{2N} \}. \quad (4)$$

$\Gamma$ is a $2N$-dimensional integer lattice, and can be written as $\Gamma = U\mathbb{Z}^{2N}$, where $U$ is a $2N$-dimensional integer matrix. Define:

$$P = U^T K^{-1} U. \quad (5)$$

$P$ is an even integer symmetric matrix with unit determinant and non-vanishing signature. The fact that it is an even integer matrix follows because the columns of $U$ generate the Lagrangian subgroup $M$, and these all have bosonic mutual and self-statistics by definition. The fact that it is symmetric and has vanishing signature follows from the fact that $K$ is symmetric and has vanishing signature. Finally, $P$ has unit determinant for the following reason. Consider any integer vector $A \in \mathbb{Z}^{2N}$, and any non-integer $2N$-component vector $x$. By definition of the Lagrangian subgroup, $\Lambda^T P x$ must be non-integer, which implies that $P x$ must be non-integer. This then implies that if $P x$ is integer for any $2N$-component vector $x$, then $x$ must be integer, which in turn implies that $P^{-1}$ is integer. $P$ and $P^{-1}$ can both be integer if and only if $P$ has unit determinant.

Since $P$ is an even symmetric integer matrix with vanishing signature and unit determinant, it follows from a mathematical theorem [34] that it is always possible to find an $SL(2N;\mathbb{Z})$ transformation $W$ such that

$$W^T P W = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad (6)$$

where $I$ is an $N \times N$ identity matrix. Thus, we consider a transformed theory:

$$\tilde{U} = W^T U W, \quad \tilde{K} = W^T K W, \quad \tilde{P} = W^T P W = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

(7)

Since $W \in SL(2N;\mathbb{Z})$, $\tilde{K}$ and $K$ describe topologically equivalent theories. Clearly, the columns of $\tilde{U}$ generate the Lagrangian subgroup $M$. Let $u_i$ denote the $i$th column of $\tilde{U}$. Let us extend $\tilde{K}$ to a $4N \times 4N$ matrix $K'$, which is composed of $\tilde{K}$ and $N$ copies of $\tau_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ along the block diagonal entries:

$$K' = \begin{pmatrix} \tilde{K} & \tau_x \\ \tau_x & \ddots \end{pmatrix}, \quad (8)$$

where the rest of the entries are zero. Again, $K'$ describes the same topological order as $K$. Now we define

$$\tilde{m}_{i}^{T} = (\tilde{u}_{1}^{T}, 0, 1, 0, 0, \cdots, 0, 0)$$

$$\tilde{m}_{2}^{T} = (\tilde{u}_{N+1}^{T}, -1, 0, 0, 0, \cdots, 0, 0)$$

$$\tilde{m}_{3}^{T} = (\tilde{u}_{2}^{T}, 0, 0, 0, 1, \cdots, 0, 0)$$

$$\tilde{m}_{4}^{T} = (\tilde{u}_{N+2}^{T}, 0, 0, -1, 0, \cdots, 0, 0)$$

$$\vdots$$

$$\tilde{m}_{2N-1}^{T} = (\tilde{u}_{N}^{T}, 0, 0, \cdots, 0, 1)$$

$$\tilde{m}_{2N}^{T} = (\tilde{u}_{2N}^{T}, 0, 0, \cdots, -1, 0) \quad (9)$$

Since the additional components added in $K'$ are all trivial degrees of freedom, the $2N$ vectors $\{\tilde{m}_{i}^{T}\}$ still generate the same Lagrangian subgroup $M$. It is easy to see that

$$m_{i}^{T} K'^{-1} m_{j}^{T} = 0. \quad (10)$$

This proves the lemma for $K$ even. In practice, in most cases of interest it is easy to find $N$ columns of $\tilde{U}$ that generate $M$ and that satisfy $\tilde{u}_{i}^{T} K'^{-1} \tilde{u}_{j} = 0$, so the above extension to a $4N$ dimensional $K$-matrix will not be necessary.

Proof for $K$ odd

Let us now consider the case where $K$ is odd (i.e., it has at least one odd element along the diagonal). As before,
we define the matrix $U$, and $P = U^T K^{-1} U$. Now, $P$ is an integer symmetric, non-singular matrix with unit determinant, non-vanishing signature, and at least one odd element along the diagonal. Under these conditions, it is always possible to find $W \in SL(2N; \mathbb{Z})$ such that

$$W^T P W = \begin{pmatrix} \mathbb{I} & 0 \\ 0 & -\mathbb{I} \end{pmatrix},$$

where $I$ is an $N \times N$ identity matrix. Thus, we consider a transformed theory:

$$\tilde{U} = W^T U,$$
$$\tilde{K} = W^T K W,$$
$$\tilde{P} = W^T P W = \begin{pmatrix} \mathbb{I} & 0 \\ 0 & -\mathbb{I} \end{pmatrix}.$$

Again, the original Lagrangian subgroup is generated by the columns of $\tilde{U}$.

Let $\tilde{u}_i$ denote the $i$th column of $\tilde{U}$, and $\tilde{u}_{i \pm} = \tilde{u}_i \pm \tilde{u}_{N+i}$, for $i = 1, \cdots, N$.

Now, as in the case where $K$ is even, let us extend the $K$-matrix to a $4N \times 4N$ matrix $K'$, which is composed of $K$ and now with $N$ copies of $\tau_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ along the block diagonal entries:

$$K' = \begin{pmatrix} \tilde{K} & \tau_z & \cdots \\ \tau_z & \cdots \\ & & \ddots \end{pmatrix},$$

where the rest of the entries are zero. In the absence of any symmetries, $K'$ describes the same topological order as $K$. Now we define

$$\tilde{m}_i^T = (\tilde{u}_{i+1}^T, 1, 1, 0, \cdots, 0, 0)$$
$$\tilde{m}_i^T = (\tilde{u}_{i-1}^T, -1, 1, 0, \cdots, 0, 0)$$
$$\tilde{m}_i^T = (\tilde{u}_{2+}^T, 0, 0, 1, 1, \cdots, 0, 0)$$
$$\tilde{m}_i^T = (\tilde{u}_{2-}^T, 0, 0, -1, 1, \cdots, 0, 0)$$
$$\vdots$$
$$\tilde{m}_{2N-1}^T = (\tilde{u}_{N+}^T, 0, 0, \cdots, 1, 1)$$
$$\tilde{m}_{2N}^T = (\tilde{u}_{N-}^T, 0, 0, \cdots, -1, 1)$$

Since the additional components added to $K'$ are all trivial degrees of freedom, the $2N$ vectors $\{\tilde{m}_i\}$ still generate the same Lagrangian subgroup $M$. It is easy to see that

$$m_i^T K'^{-1} m_j^T = 0.$$

This proves the lemma for $K$ odd.
