I. INTRODUCTION

Traditionally, quantum entanglement was believed to be the unique quantum correlation that enables us to overcome the limit of classical computational models [1–3]. However, it has been recently shown that entanglement is not the only quantum correlation that can be used to obtain a quantum speed-up; there exist quantum computational models such as the deterministic quantum computation with one qubit (DCQ1), which only uses separable states [4–6]. The resource believed to provide an enhancement in this computational task is quantum discord (QD) [7,8].

Besides quantum computational protocols, many other remarkable applications of QD have also been proposed such as the characterization of quantum phase transitions [9] and the dynamics of quantum systems under decoherence [10]. QD is thus identified as a general resource in quantum information processing.

Since the original definition of QD in bipartite quantum systems [7], which considers a set of local measurements only on one subsystem, a symmetric extension of QD was suggested, namely global quantum discord (GQD) [11], with analytical expressions for some classes of quantum states [12]. Whereas QD is defined in terms of von Neumann entropy of quantum states, a generalized version of QD in terms of Tsallis entropy has also been proposed for bipartite quantum systems [13,14].

For efficient applications of QD as a resource in quantum information and communication protocols, it is an important task to characterize its possible distribution or shareability in multiparty quantum systems. For examples, quantum entanglement cannot be shared freely in multiparty quantum systems, and this restricted shareability of entanglement is known as the monogamy of entanglement (MoE) [15].

Mathematically, MoE in multiparty quantum systems is characterized as a trade-off inequality in terms of bipartite entanglement measures. The first monogamy inequality of entanglement was established in three-qubit systems using tangle as the bipartite entanglement measure [16]. Since then, there has been intensive research contributed on this topic for possible generalization of the monogamy inequality into multiparty higher-dimensional quantum systems [17]. Recently, it has been shown that the entanglement monogamy inequality holds for arbitrarily dimensional multiparty quantum systems in terms of the squashed entanglement [18].

MoE plays a crucial role in many quantum information processing tasks. In quantum key-distribution protocols, for example, the possible amount of information an eavesdropper could obtain about the secret key can be restricted by MoE, which is the fundamental concept of security proof [19]. Thus the founding principle of quantum cryptographic schemes that an eavesdropper cannot obtain any information without disturbance is guaranteed by MoE, the law of quantum physics, rather than assumptions on the difficulty of computation.

Because MoE is a property of a typical quantum correlation, quantum entanglement, without any classical counterpart, it is also natural and meaningful to investigate whether other quantum correlations such as QD or GQD can have such restricted shareability or distribution in multiparty quantum systems, which still have many important open questions [16,17,20,21].

In this paper, using Tsallis-$q$ entropy, we propose a one-parameter class of quantum correlation measures, $q$-global quantum discord ($q$-GQD), which include GQD as a special case. We provide an analytic expression of $q$-GQD for some classes of multiqubit states and show that the pairwise quantum correlations in terms of global quantum-$q$ discord can be monogamous in multiparty quantum systems.

This paper is organized as follows. In Sec. II, we briefly recall the motivation and definitions of QD and GQD. In Sec. III, we introduce the concept of $q$-GQD in multiparty quantum systems as well as its properties. In Sec. IV, we provide an analytical expression of $q$-GQD for some classes of multiqubit states, and we show a sufficient condition for monogamy inequality of $q$-GQD in multiparty quantum systems in Sec. V. In Sec. VI, we summarize our results.

II. QUANTUM DISCORD

A. Quantum discord in bipartite and multipartite quantum systems

For a bipartite quantum state $\rho^{AB}$ and a set of local von Neumann measurement $\{\Pi_j^B\}$ on subsystem $B$, the quantum state of subsystem $A$ after performing the measurement $\{\Pi_j^B\}$ and obtaining the measurement outcome $j$ is $\rho_j^A = \text{tr}_B[(I_A \otimes \Pi_j^B)\rho^{AB}] / p_j$, with probability $p_j = \text{tr}[(I_A \otimes \Pi_j^B)\rho^{AB}]$. The average of the von Neumann entropies $S(\rho_j^A)$ of $\rho_j^A$ weighted...
by probabilities $p_j$ yields to the conditional entropy of subsystem $A$ given the complete measurement $\{\Pi^A_j\}$ on subsystem $B$,

$$S^{(\Pi^A_j)}(\rho^A) = \sum_j p_j S(\rho^A_j),$$  \hspace{1cm} (1)

where $S(\rho) = -\text{tr}\rho \log_2 \rho$ is the von Neumann entropy of the quantum state $\rho$.

We note that the possible inequivalent concepts of quantum mutual information we can consider here are

$$\mathcal{I}(\rho^{AB}) = S(\rho^A) + S(\rho^B) - S(\rho^{AB})$$  \hspace{1cm} (2)

and

$$J^{(\Pi^A_j)}(\rho^{AB}) = S(\rho^A) - S^{(\Pi^A_j)}(\rho^A),$$  \hspace{1cm} (3)

where $\rho^A = \text{tr}_B \rho^{AB}$, $\rho^B = \text{tr}_A \rho^{AB}$ are the reduced density matrices of $\rho^{AB}$ on subsystems $A$ and $B$, respectively. In other words, Eq. (2) is a straightforward generalization of the classical mutual information in terms of the quantum conditional entropy $S^{(\Pi^A_j)}(\rho^A) = S(\rho^A) - S(\rho^B)$, whereas Eq. (3) can be considered as the measurement-induced quantum mutual information using Eq. (1).

The QD of $\rho^{AB}$ is then defined by the minimized difference between these two inequivalent generalizations of classical mutual information over all possible von Neumann measurements $\{\Pi^A_j\}$ on subsystem $B$ [7].

$$\delta^-(\rho^{AB}) = \min_{\{\Pi^A_j\}} [\mathcal{I}(\rho^{AB}) - J^{(\Pi^A_j)}(\rho^{AB})].$$  \hspace{1cm} (4)

QD is not symmetric under the interchange of subsystems to be measured,

$$\delta^-(\rho^{AB}) \neq \delta^-(\rho^{BA}),$$  \hspace{1cm} (5)

and it is non-negative for any bipartite quantum state $\rho^{AB}$ [7].

QD has been generalized into multiparty quantum systems [22]: for an $n$-party quantum states $\rho^{A_1 \cdots A_n} = \rho^A$ with the reduced density matrix $\rho^A_k$ of the subsystem $A_k$ for each $k = 1, \ldots, n$, its quantum mutual information is given by

$$\mathcal{I}(\rho^A) = \sum_{i=1}^n S(\rho^{A_i}) - S(\rho^A).$$  \hspace{1cm} (6)

(Throughout this paper, the bold superscript $A$ in $\rho^A$ denotes an $n$-party quantum system unless otherwise specified.) By using the notation of quantum conditional entropy

$$S(\rho^A_k|A_i) = S(\rho^A_k) - S(\rho^{A_i}),$$  \hspace{1cm} (7)

where the superscript $A_i$ stands for the quantum systems complement to $A_k$, we can rewrite the quantum mutual information in Eq. (6) as

$$\mathcal{I}(\rho^A) = \sum_{i \neq k} S(\rho^{A_i}) - S(\rho^{A_i|A_k}).$$  \hspace{1cm} (8)

Now let us consider the situation that a von Neumann measurement $\{\Pi^A_j\}$ is performed on subsystem $A_k$. The postmeasurement joint state of the systems $\overline{A}_k$ is given by

$$\rho^A_k = \text{tr}_{A_i}[(P^A_j|A_k)\rho^A_k]/p^A_j,$$  \hspace{1cm} (9)

where $P^A_j = (I \otimes \cdots \otimes \Pi^A_j \otimes \cdots \otimes I)$ is the measurement operator acting only on the subsystem $A_k$ and $p^A_j = \text{tr}[\rho^A_k \rho^A_k]$ is the probability of the measurement result on subsystem $A_k$. Similar to Eq. (1), the average of the von Neumann entropies $S(\rho^A_k)$ weighted by the probabilities $p^A_j$ leads us to the quantum conditional entropy given the complete measurement $\{\Pi^A_j\}$ on the system $A_k$,

$$S^{(\Pi^A_j)}(\rho^A_k) = \sum_j p^A_j S(\rho^A_k).$$  \hspace{1cm} (10)

Thus the quantum mutual information, induced by the von Neumann measurement $\{\Pi^A_j\}$, is defined by

$$J^{(\Pi^A_j)}(\rho^A_k) = \sum_{i \neq k} S(\rho^{A_i}) - S^{(\Pi^A_j)}(\rho^{A_i}),$$  \hspace{1cm} (11)

which is an analogous quantity of Eq. (3). The QD for the $n$-party state $\rho^A$ is defined as the minimized difference between Eqs. (8) and (11) over all possible von Neumann measurements $\{\Pi^A_j\}$ on subsystem $A_k$,

$$\delta^A_k(\rho^A) = \min_{\{\Pi^A_j\}} \left[\mathcal{I}(\rho^A) - J^{(\Pi^A_j)}(\rho^A)\right].$$  \hspace{1cm} (12)

B. Global quantum discord

For a bipartite quantum state $\rho^{AB}$, its mutual information $\mathcal{I}(\rho^{AB})$ in Eq. (2) can be expressed in terms of the relative entropy between $\rho^{AB}$ and $\rho^A \otimes \rho^B$,

$$\mathcal{I}(\rho^{AB}) = S(\rho^{AB} || \rho^A \otimes \rho^B),$$  \hspace{1cm} (13)

where $S(\rho || \sigma) = \text{tr}\rho \log_2 \rho - \text{tr}\rho \log_2 \sigma$ is the quantum relative entropy of $\rho$ and $\sigma$.

In order to express the measurement-induced quantum mutual information in Eq. (3) in terms of quantum relative entropy, we consider a nonselective von Neumann measurement $\Phi = \{\Pi^B_j = |b_j\rangle \langle b_j|\}$ on subsystem $B$, which yields to the quantum state

$$\Phi(\rho^{AB}) = \sum_j (I \otimes \Pi^B_j)\rho^{AB}(I \otimes \Pi^B_j)$$

$$= \sum_j p_j \rho^A_j \otimes |b_j\rangle \langle b_j|,$$  \hspace{1cm} (14)

and its reduced density matrix of subsystem $B$

$$\Phi(\rho^B) = \text{tr}_A[\Phi(\rho^{AB})] = \sum_j p_j |b_j\rangle \langle b_j|. $$  \hspace{1cm} (15)

Because $\{|b_j\rangle\}$ forms an orthonormal basis for subsystem $B$, we have

$$S(\Phi(\rho^{AB})) = H(p) + \sum_j p_j S(\rho^A_j)$$  \hspace{1cm} (16)

and

$$S(\Phi(\rho^B)) = H(P),$$  \hspace{1cm} (17)

where $H(P)$ is the Shannon entropy of the probability ensemble $P = \{p_i\}$. Thus we can rewrite the measurement-induced
From Eqs. (13) and (18), the definition of QD in Eq. (4) can be expressed in terms of the relative entropy as quantum mutual information in Eq. (3) as

\[ \delta^-(\rho^{AB}) = \min_{\{\Pi_j^R\}} [S(\rho^{AB}) - S(\rho^{A}) - S(\rho^{B})] \]

\[ = S(\Phi^{AB} || \rho^{A} \otimes \Phi^{B}) - S(\Phi^{AB}) \]

\[ = \mathcal{I}(\Phi^{AB}). \]  

From Eqs. (13) and (18), the definition of QD in Eq. (4) can be expressed in terms of the relative entropy as quantum mutual information in Eqs. (2) and (3) for a bipartite state \( \rho^{AB} \) on subsystems A and B,

\[ D(\rho^{AB}) = \min_{\{\Pi_j^R \otimes \Pi_j^B\}} \{\mathcal{I}(\rho^{AB}) - \mathcal{I}(\rho^{A})\}, \]

where

\[ \Phi(\rho^{AB}) = \sum_{j_1,j_2} (\Pi_{j_1}^A \otimes \Pi_{j_2}^B) \rho^{AB} (\Pi_{j_1}^A \otimes \Pi_{j_2}^B), \]

and the minimization is over all possible von Neumann measurements \( \{\Pi_j^R\} \) on subsystems A and B, respectively.

Unlike QD, it is clear from the definition that GQD is symmetric under the permutation of subsystems. GQD was also shown to be non-negative for an arbitrary quantum state. Moreover GQD has a useful operational interpretation; in the absence of GQD, the quantum state simply describes a classical probability distribution.

The definition of GQD in Eq. (20) was also generalized to multiparty quantum systems; for an n-party quantum state \( \rho^A \), its GQD is defined as

\[ D(\rho^A) = \min_{\{\Pi_i\}} [\mathcal{I}(\rho^A) - \mathcal{I}(\rho^A)], \]

where \( \Phi(\rho^A) = \sum_{j} \Pi_j^A \rho^A \Pi_j^A \) is the density operator after a nonselective local measurement \( \Phi = \{\Pi_j = \Pi_{j_1}^A \otimes \Pi_{j_2}^A \otimes \cdots \otimes \Pi_{j_n}^A\} \) with \( j \) denoting the index string \( (j_1, \ldots, j_n) \),

\[ \mathcal{I}(\rho^A) = \sum_{k=1}^n S(\Phi(\rho^A)) - S(\Phi(\rho^A)) \]

and

\[ \Phi(\rho^A) = tr_{\Pi_k} \Phi(\rho^A) \]  

is the reduced density operator of \( \Phi(\rho^A) \) onto the subsystem \( A_k \) for each \( k = 1, \ldots, n. \)

III. GLOBAL QUANTUM DISCORD IN TERMS OF TSALLIS-q ENTROPY

In this section, we first recall the definition of Tsallis-q entropy of quantum states \( [23,24] \) and bipartite QD concerned with Tsallis-q entropy \([14]\). We then introduce a one-parameter class of GQD in terms of Tsallis-q entropy and investigate its properties.

A. Tsallis-q entropy and quantum discord

Using the generalized logarithmic function with respect to the parameter \( q \) (namely q logarithm)

\[ \ln_q x = \frac{x^{1-q} - 1}{1-q}, \]

quantum Tsallis-q entropy of a quantum state \( \rho \) is defined as

\[ S_q(\rho) = -tr \rho^q \ln_q \rho - \frac{1 - tr \rho^q}{q - 1} \]

for \( q > 0, q \neq 1 \) \([24]\). Although the quantum Tsallis-q entropy has a singularity at \( q = 1 \), it is straightforward to check that it converges to von Neumann entropy when \( q \) tends to 1,

\[ \lim_{q \rightarrow 1} S_q(\rho) = S(\rho). \]

Tsallis entropy has been widely used in many areas of quantum information theory such as the conditions for separability of quantum states \([25-27]\) and the characterization of classical statistical correlations inherent in quantum states \([28]\). There are also discussions about using the nonextensive statistical mechanics to describe quantum entanglement \([29]\). Similar to other entropy functions, Tsallis entropy is non-negative for any quantum state.

Using Tsallis-q entropy, QD was generalized to a one-parameter class of quantum correlation measure, namely q-quantum discord (q-QD) \([13,14]\). The inequivalent expressions of quantum mutual information in Eqs. (2) and (3) for a bipartite quantum state \( \rho^{AB} \) can be generalized in terms of Tsallis-q entropy as

\[ \mathcal{I}_q(\rho^{AB}) = S_q(\rho^A) + S_q(\rho^B) - S_q(\rho^{AB}) \]

and

\[ J_q(\rho^{AB}) = S_q(\rho^A) - S_q(\rho^{AB}) \]

where

\[ S_q^{\Pi_j^R}(\rho^A) = \sum_{j} p_j^q S_q(\rho^A_j) \]

is the q-expected value of Tsallis-q entropies \( S_q(\rho^A_j) \) \([14]\). Then the q-QD for a bipartite state \( \rho^{AB} \) is defined as

\[ \delta_q^-(\rho^{AB}) = \min_{\{\Pi_j\}} [\mathcal{I}_q(\rho^{AB}) - J_q^{\Pi_j}(\rho^{AB})], \]

where the minimization is taken over all possible sets of rank-one measurement \( \{\Pi_j\} \) on subsystem B.

Due to the continuity of Tsallis-q entropy with respect to the parameter \( q \), q-QD converges to QD when \( q \) tends to 1, and therefore the non-negativity of q-QD follows from that of QD as \( q \) tends to 1. Furthermore, the following proposition provides a possible range of \( q \) where q-QD is nonnegative \([13,14]\).

Proposition 1. For any bipartite state \( \rho^{AB} \) and \( 0 < q \leq 1 \),

\[ \delta_q^-(\rho^{AB}) \geq 0. \]
B. q-global quantum discord

For a nonselective von Neumann measurement \( \Phi = \{ \Pi_j = |b_j\rangle\langle b_j| \} \) on subsystem \( B \) of \( \rho^{AB} \), which yields a bipartite quantum state \( \Phi(\rho^{AB}) \) in Eq. (14) and the reduced density matrix \( \rho_B \) in Eq. (15), we have
\[
S_q(\Phi(\rho^{AB})) = \frac{1 - \text{tr}(\sum_j p_j \rho_A^j \otimes |b_j\rangle\langle b_j|)}{q - 1} = \frac{1 - \text{tr}(\sum_j p_j \rho_A^j)^q}{q - 1} + \sum_j p_j \frac{1 - \text{tr}(\rho_A^j)^q}{q - 1} = S_q(\rho_B) + \sum_j p_j S_q(\rho_A^j),
\]
where the last equality is from the definition of Tsallis-q entropy for quantum states \( \Phi(\rho_B) \) and \( \rho_A^j \), respectively.

From Eq. (29) together with Eqs. (30) and (33), we have
\[
J_q^\rho(\rho^{AB}) = S_q(\rho_A^j) + S_q(\Phi(\rho^{AB})) - S_q(\Phi(\rho^{AB})) = I_q(\Phi(\rho^{AB})),
\]
which leads us to the following lemma.

Lemma 1. For a bipartite state \( \rho^{AB} \), its q-quantum discord can be expressed as
\[
\delta_q(\rho^{AB}) = \min_\phi [I_q(\rho^{AB}) - I_q(\Phi(\rho^{AB}))],
\]
where the minimization is taken over all possible von Neumann measurements \( \Phi \) of subsystem \( B \).

Now we introduce the concept of q-global quantum discord (q-GQD) as a symmetric generalization of q-QD in Lemma 1.

Definition 1. For a bipartite state \( \rho^{AB} \), its q-GQD is defined as
\[
D_q(\rho^{AB}) = \min_\Phi [I_q(\rho^{AB}) - I_q(\Phi(\rho^{AB}))],
\]
where the minimization is over all possible local von Neumann measurements \( \Phi = \{ \Pi_j = \Pi_i^A \otimes \Pi_j^B \} \) on both subsystems \( A \) and \( B \).

We also propose a systematic extension of q-GQD in Definition 1 into multipart quantum systems; as a generalization of quantum mutual information of a n-party quantum state \( \rho^{A_1\cdots A_n} \) in Eq. (6), we define the quantum mutual information in terms of Tsallis-q entropy as
\[
I_q(\rho^A) = \sum_{i=1}^n S_q(\rho^A_i) - S_q(\rho^A),
\]
with the reduced density matrix
\[
\Phi(\rho^{A_i}) = \text{tr}_{\overline{A_i}} \Phi(\rho^A)
\]
on subsystem \( A_i \) for each \( i = 1, \ldots, n \).

Definition 2. For an n-party quantum state \( \rho^{A_1\cdots A_n} \), its q-GQD is defined as
\[
D_q(\rho^{A_1\cdots A_n}) = \min_\Phi [I_q(\rho^{A_1\cdots A_n}) - I_q(\Phi(\rho^{A_1\cdots A_n}))],
\]
where the minimization is over all possible local von Neumann measurements \( \Phi = \{ \Pi_j = \Pi_i^{A_1} \otimes \Pi_j^{A_2} \otimes \cdots \otimes \Pi_j^{A_n} \} \).

Similar to GQD, q-GQD is symmetric under the permutation of subsystems. Moreover, due to the minimization character over all possible local von Neumann measurements, it is also clear that q-GQD is invariant under local unitary transformations, that is,
\[
D_q(\rho^A) = D_q(U\rho^A U^\dagger),
\]
for any local unitary operator \( U = U^{A_1} \otimes \cdots \otimes U^{A_n} \).

The following theorem shows that the non-negativity of q-GQD is assured for a selective choice of the parameter \( q \).

Theorem 2. For any n-party quantum state \( \rho^A \), its q-GQD is nonnegative for \( 0 < q < 1 \),
\[
D_q(\rho^A) \geq 0.
\]
Proof. For a n-party quantum state \( \rho^A \), and a set of local von Neumann measurement \( \Phi = \{ \Pi_j = \Pi_i^{A_1} \otimes \Pi_j^{A_2} \otimes \cdots \otimes \Pi_j^{A_n} \} \) with the index string \( j = (j_1, \ldots, j_n) \), let \( \Phi_j = \{ \rho_j^k = I \otimes \cdots \otimes \Pi_j^{A_k} \otimes \cdots \otimes I \} \) and
\[
\Phi^{A_k}(\rho^A) = \sum_{j_k} P_{j_k}^{A_k} \rho^A P_{j_k}^{A_k},
\]
for each \( k = 1, 2, \ldots, n \). In other words, \( \Phi^{A_k}(\rho^A) \) is the n-party quantum state after the nonselective local measurement \( \{ \Pi_j^{A_k} \} \) on only subsystem \( A_k \) for each \( k = 1, 2, \ldots, n \).

We note that for any two subsystems \( A_i \) and \( A_k \) such that \( i \neq k \leq n \), we have
\[
\Phi^{A_i}(\rho^{A_i}) = \Phi^{A_k}(\rho^{A_k}).
\]

Using the notation \( \Phi^{A_k}(\rho^{A_k}) = \Phi^{A_k}(\rho^{A_k}) \), we define \( \sigma_k^A \) as the n-party quantum state after the nonselective local measurements \( \{ \Pi_j^{A_1} \}, \{ \Pi_j^{A_2} \}, \ldots, \{ \Pi_j^{A_n} \} \), on the first k subsystems \( A_1, A_2, \ldots, A_k \) for each \( k = 0, 1, 2, \ldots, n \), that is,
\[
\sigma_k^A = \Phi^{A_1A_2\cdots A_k}(\rho^A), \sigma_0^A = \rho^A
\]
and
\[
\sigma_n^A = \Phi^{A_1A_2\cdots A_n}(\rho^A) = \Phi(\rho^A).
\]

By assuming that \( \Phi = \{ \Pi_j = \Pi_i^{A_1} \otimes \Pi_j^{A_2} \otimes \cdots \otimes \Pi_j^{A_n} \} \) is an optimal measurement for \( D_q(\rho^{A_1\cdots A_n}) \), we have
\[
D_q(\rho^{A_1\cdots A_n}) = I_q(\rho^{A_1\cdots A_n}) - I_q(\Phi(\rho^{A_1\cdots A_n})) = I_q(\sigma_0^A) - I_q(\sigma_n^A)
\]
\[
= \sum_{k=0}^{n-1} [I_q(\sigma_k^A) - I_q(\sigma_{k+1}^A)]
\]
\[
= \sum_{k=0}^{n-1} [I_q(\sigma_k^A) - I_q(\Phi(\sigma_k^A))].
\]
Now, for each \( k = 0, \ldots, n - 1 \), let us consider \( \sigma_k^A = \sigma_k^{A_1, A_2, \ldots, A_n} \) as a bipartite quantum state \( \sigma_k^{A_1, A_1} \) with respect to the bipartition between the subsystems \( A_{k+1} \) and its complement, \( \overline{A}_{k+1} \). Then we have
\[
I_q (\sigma_k^A) - I_q \left( \Phi_{A_{k+1}}^{\Lambda} (\sigma_k^A) \right) \geq \min_{\Phi_{A_{k+1}}^{\Lambda}} \left\{ I_q (\sigma_k^A) - I_q \left( \Phi_{A_{k+1}}^{\Lambda} (\sigma_k^A) \right) \right\} = \delta_q^{-\Lambda}(\sigma_k^{A_{k+1}, A_{k+1}}) \geq 0, \tag{48}
\]
where \( \delta_q^{-\Lambda}(\sigma_k^{A_{k+1}, A_{k+1}}) \) is the \( q \)-QD of the bipartite quantum state \( \sigma_k^{A_{k+1}, A_{k+1}} \), and the last inequality holds for \( 0 < q \leq 1 \) by Proposition 1. From Eqs. (47) and (48), we have
\[
D_q (\rho^A) = \sum_{k=0}^{n-1} \delta_q^{-\Lambda}(\sigma_k^{A_{k+1}, A_{k+1}}) \geq 0, \tag{49}
\]
which completes the proof.

### IV. Analytic Evaluation

As a measure of quantum correlation among composite systems, \( q \)-QGD is a well-defined quantity for arbitrary quantum states. However, it is hard to evaluate due to the minimization over all possible local von Neumann measurements in the definition. In this section, by investigating the monotonicity of Tsallis-\( q \) entropy under majorization of real vectors, we provide an analytic way of evaluating \( q \)-QGD for some classes of multiqubit quantum states.

Let us recall the definition of Tsallis-\( q \) entropy for a probability distribution \( P = (p_j) \) \cite{23},
\[
H_q (P) = - \sum_j p_j^q \ln p_j = \frac{1 - \sum_j p_j^q}{q - 1}. \tag{50}
\]
For a quantum state \( \rho \) with spectral decomposition \( \rho = \sum_j \lambda_j |\psi_j\rangle \langle \psi_j| \), it is straightforward to check that the quantum Tsallis-\( q \) entropy of \( \rho \) in Eq. (26) is in fact the Tsallis-\( q \) entropy of the spectrum of \( \rho \), that is,
\[
S_q (\rho) = H_q (\Lambda), \tag{51}
\]
where \( \Lambda = (\lambda_j) \).

Now we consider a special property of Tsallis-\( q \) entropy, namely Schur concavity, and before this, we first introduce the concept of majorization among real vectors \cite{30}. For real vectors \( \vec{x}, \vec{y} \in \mathbb{R}^n \) such that \( \vec{x} = (x_1, x_2, \ldots, x_n) \) and \( \vec{y} = (y_1, y_2, \ldots, y_n) \), \( \vec{x} \) is said to be majorized by \( \vec{y} \), denoted by \( \vec{x} < \vec{y} \) if
\[
\sum_{j=1}^{k} x_j \leq \sum_{j=1}^{k} y_j
\]
for \( j = 1, 2, \ldots, n - 1 \), and
\[
\sum_{j=1}^{n} x_j = \sum_{j=1}^{n} y_j. \tag{53}
\]
A real-valued function \( \phi \) defined on \( \mathbb{R}^n \) is said to be Schur concave on \( \mathbb{R}^n \) if
\[
\vec{x} < \vec{y} \text{ on } \mathbb{R}^n \Rightarrow \phi (\vec{x}) \geq \phi (\vec{y}). \tag{54}
\]

for any \( \vec{x}, \vec{y} \in A \). We further note that \( \phi \) is said to be symmetric if
\[
\phi (\vec{x}) = \phi (M \vec{x}) \tag{55}
\]
for any \( n \)-dimensional permutation \( M \), and \( \phi \) is said to be concave if
\[
\phi (p \vec{x} + (1 - p) \vec{y}) \geq p \phi (\vec{x}) + (1 - p) \phi (\vec{y}), \tag{56}
\]
for any \( \vec{x}, \vec{y} \in \mathbb{R}^n \) and \( 0 \leq p \leq 1 \).

For a sufficient condition of Schur concavity, we have the following proposition \cite{30}:

**Proposition 2.** If a real-valued function \( \phi \) defined on \( \mathbb{R}^n \) is symmetric and concave, then \( \phi \) is Schur concave.

Now we show the monotonicity of Tsallis-\( q \) entropy under majorization.

**Lemma 3.** For a given probability distributions \( P = (p_1, p_2, \ldots, p_n) \) and \( Q = (q_1, q_2, \ldots, q_n) \) satisfying \( 1 \geq p_1 \geq \cdots \geq p_n \geq 0, 1 \geq q_1 \geq \cdots \geq q_n \geq 0 \) and \( \sum_{i=1}^{n} p_i = \sum_{i=1}^{n} q_i = 1 \), if
\[
\sum_{i=1}^{k} p_i \leq \sum_{i=1}^{k} q_i, \tag{57}
\]
for each \( k = 1, \ldots, n \), then
\[
H_q (P) \geq H_q (Q), \tag{58}
\]
where \( H_q (P) \) and \( H_q (Q) \) are Tsallis-\( q \) entropies of the probability distributions \( P \) and \( Q \) respectively.

**Proof.** For the closed unit interval \( I = [0, 1] \) of \( \mathbb{R} \), we can consider the probability distributions \( P \) and \( Q \) as \( n \)-dimensional vectors in \( P^n \subset \mathbb{R}^n \),
\[
P \leftrightarrow \bar{p} = (p_1, p_2, \ldots, p_n), \tag{59}
Q \leftrightarrow \bar{q} = (q_1, q_2, \ldots, q_n).
\]
(Thus we use the notation \( H_q (\bar{p}) \) equivalently as \( H_q (P) \).)

Because \( P \) and \( Q \) are probability distributions, Eq. (57) implies that \( \bar{p} \) is majorized by \( \bar{q} \), thus showing Eq. (58) is equivalent to show that Tsallis-\( q \) entropy is Schur concave. Furthermore, Proposition 2 says that it is sufficient to show that Tsallis-\( q \) entropy is symmetric and concave.

We first note that Tsallis-\( q \) entropy is clearly symmetric by its definition in Eq. (50); that is, for any probability distribution \( P = \bar{p} \in P^n \),
\[
S_q (\bar{p}) = S_q (M \bar{p}), \tag{60}
\]
for any \( n \)-dimensional permutation \( M \). The concavity of Tsallis-\( q \) entropy follows from a simple calculus; for any probability distribution \( \bar{p} \in P^n \) with the normalization condition \( \sum_{k=1}^{n} p_k = 1 \), by introducing the Lagrange multiplier \( \lambda \), we have the Hessian matrix
\[
\frac{\partial^2}{\partial p_i \partial p_j} \left[ S_q (\bar{p}) - \lambda \left( \sum_{k=1}^{n} p_k - 1 \right) \right] = -q p_i^{-2} \delta_{ij}, \tag{61}
\]
which is clearly negative semidefinite for \( 1 \leq i, j \leq n \), and \( 0 < q \). Thus Tsallis-\( q \) entropy is Schur concave for \( 0 < q \), and this completes the proof.

Let us consider a one-parameter class of multiqubit states,
\[
\rho_{\mu} = (1 - \mu) \frac{I^{\otimes n}}{2^n} + \mu |\psi\rangle \langle \psi| \tag{62}
\]
for \( \mu \in [0,1] \), where \( I \) is the 2 \( \times \) 2 identity operator and \( |\psi\rangle = ((00\ldots0) + (11\ldots1))/\sqrt{2} \). The class of states in Eq. (62) is known as the \( n \)-qubit Werner-GHZ state, which is a mixture of a fully mixed state (thus no \( q \)-GQD) and a maximally correlated pure state (thus maximal \( q \)-GQD). The following theorem allows an analytic evaluation of \( q \)-GQD for \( n \)-qubit Werner-GHZ states.

**Theorem 4.** For the \( n \)-qubit Werner-GHZ state \( \rho_\mu = (1 - \mu)I^{\otimes n}/2^n + \mu|\psi\rangle\langle\psi| \), its \( q \)-GQD is

\[
D_q(\rho_\mu) = (1 - \mu)q + \mu \ln q \left( \frac{1 - \mu}{2^n} + \mu \right) + \mu q \ln \left( \frac{1 - \mu}{2^n} \right) - 2 \frac{1 - \mu}{2^n} \ln \left( \frac{1 - \mu}{2^n} + \mu \right). \tag{63}
\]

An analytic evaluation of GQD for \( n \)-qubit Werner-GHZ states was proposed in Ref. [12], and our proof method for Theorem 4 follows the construction therein.

**Proof.** We first note that the reduced density matrix \( \rho_\mu^{(i)} \) of \( \rho_\mu \) onto each one-qubit subsystem \( A_1, \ldots, A_n \) is proportional to identity operator \( I/2 \). In this case, it follows from the definition that the \( q \)-GQD of \( \rho_\mu \) is simplified as

\[
D_q(\rho_\mu) = -S_q(\rho_\mu) + \min_{\Phi} \Phi S_q(\Phi(\rho_\mu)) \tag{64}
\]

with the minimization over all von Neumann measurements \( \Phi \). For \( \rho_\mu \), it has 2\( n \) eigenvalues

\[
\left\{ \frac{1 - \mu}{2^n} + \mu, \frac{1 - \mu}{2^n}, \frac{1 - \mu}{2^n}, \ldots, \frac{1 - \mu}{2^n} \right\}, \tag{65}
\]

\( S_q(\rho_\mu) \) in Eq. (64) can be easily calculated.

We also note that a von Neumann measurement on single qubit can be expressed as

\[
\Pi_0 = \frac{1}{2}(I + \vec{\Pi} \cdot \vec{\sigma}), \quad \Pi_1 = \frac{1}{2}(I - \vec{\Pi} \cdot \vec{\sigma}), \tag{66}
\]

where \( \vec{\Pi} = (\alpha, \beta, \gamma) \) is a real vector with unit length and \( \vec{\sigma} = (\sigma_x, \sigma_y, \sigma_z) \) with Pauli matrices \( \sigma_x, \sigma_y, \sigma_z \).

Now, for any \( n \)-qubit local projective measurement \( \Phi \), we can identify it as \( \Phi = \{\Pi_1\} \otimes \cdots \otimes \{\Pi_n\} \) for some \( n \) number of real vectors with unit length \( \Pi_i = (\alpha_i, \beta_i, \gamma_i) \) for \( i = 1, \ldots, n \).

After a bit of algebra, it can be shown that the quantum state \( \Phi(\rho_\mu) \) obtained after a nonselective von Neumann measurement \( \Phi \) on each subsystem has 2\( n \) eigenvalues \( \{1 - \mu \} \) and \( \{1/2^n\} \) in Eq. (67), in decreasing order, it is always majorized by the vector with \( \gamma_i = 1 \) for all \( i \), that is

\[
\left( \frac{1 - \mu}{2^n}, \frac{1 - \mu}{2^n}, \frac{1 - \mu}{2^n}, \ldots, \frac{1 - \mu}{2^n} \right). \tag{68}
\]

Thus by the monotonicity of Tsallis-\( q \)-entropy under majorization in Lemma 3, we assert that \( S_q(\Phi(\rho_\mu)) \) achieves its minimum when \( \gamma_i = 1 \) for all \( i \). From Eqs. (65) and (68), we are ready to have an analytic evaluation of Eq. (64), which leads us to Eq. (63).

Now, let us consider another class of multiqubit states whose analytic evaluation of \( q \)-GQD is feasible.

**Theorem 5.** Let us consider an \( n \)-qubit state

\[
\rho = \frac{1}{2^n} \left( I^{\otimes n} + c_1 \sigma_x^{\otimes n} + c_2 \sigma_y^{\otimes n} + c_3 \sigma_z^{\otimes n} \right), \tag{69}
\]

where \( I \) is 2 \( \times \) 2 identity operator, and \( c_1, c_2, \) and \( c_3 \) are real numbers constrained by \( 0 \leq d = \sqrt{c_1^2 + c_2^2 + c_3^2} \leq 1 \). If \( n \) is odd,

\[
D_q(\rho) = -\frac{2^{n-1}}{q-1} \left[ \left( \frac{1+c}{2^n} \right)^q + \left( \frac{1-c}{2^n} \right)^q - \left( \frac{1+d}{2^n} \right)^q - \left( \frac{1-d}{2^n} \right)^q \right]. \tag{70}
\]

where \( c = \max\{|c_1|, |c_2|, |c_3|\} \). If \( n \) is even,

\[
D_q(\rho) = -\frac{2^{n-2}}{q-1} \left[ 2 \left( \frac{1+c}{2^n} \right)^q + 2 \left( \frac{1-c}{2^n} \right)^q - 4 \sum_{j=1}^{\lambda_4} \left( \frac{\lambda_j}{2^n} \right)^q \right], \tag{71}
\]

with \( \lambda_1, \lambda_2, \lambda_3, \lambda_4 \in [0,1] \) such that

\[
\begin{align*}
\lambda_1 &= 1 + c_1 + c_1 + (-1)^{n/2}c_2, \\
\lambda_2 &= 1 + c_3 - c_1 - (-1)^{n/2}c_2, \\
\lambda_3 &= 1 - c_1 + c_1 - (-1)^{n/2}c_2, \\
\lambda_4 &= 1 - c_3 - c_1 + (-1)^{n/2}c_2.
\end{align*} \tag{72}
\]

Our proof method for Theorem 5 is based on the construction in Ref. [12], which is an analytic evaluation of GQD for the class of states in Eq. (69).

**Proof.** Due to the traceless property of Pauli matrices, it is clear that the reduced density matrix \( \rho_\mu^{(i)} \) of \( \rho \) onto each one-qubit subsystem \( A_1, \ldots, A_n \) is proportional to identity operator \( I/2 \). Thus the \( q \)-GQD of \( \rho \) is simplified as

\[
D_q(\rho) = -S_q(\rho) + \min_{\Phi} \Phi S_q(\Phi(\rho)) \tag{73}
\]

with the minimization over all local von Neumann measurements \( \Phi \).

We also note that \( \rho \) has nonzero elements only on the principle diagonal and the antidiagonal, thus a direct calculation of the characteristic polynomial \( \det(\rho - \lambda I^{\otimes n}) = 0 \) leads us to the eigenvalues of \( \rho \); if \( n \) is odd, the eigenvalues of \( \rho \) are

\[
\left\{ \frac{1}{2^n} \left( 1 \pm \sqrt{c_1^2 + c_2^2 + c_3^2} \right) \right\} = \left\{ \frac{1}{2^n} (1 \pm d) \right\}. \tag{74}
\]
each of them has multiplicity $2^{n-1}$. When $n$ is even, the eigenvalues of $\rho$ are
\[
\left( \frac{1 + c_3}{2^n} + c_1 + (-1)^{n/2}c_2, \frac{1 - c_3}{2^n} + c_1 - (-1)^{n/2}c_2 \right),
\]
(75)
each of them with multiplicity $2^{n-2}$.

Similar to the proof of Theorem 4, by identifying an $n$-qubit local projective measurement $\Phi$ with a set of real vectors $\{\tilde{\Pi}_i = (\alpha_i, \beta_i, \gamma_i)\}$ for $i = 1, \ldots, n$, the eigenvalues of $\Phi(\rho)$ can be obtained as
\[
\left\{ \frac{1}{2^n} \left[ 1 \pm \left( c_1 \prod_{i=1}^{n} \alpha_i + c_2 \prod_{i=1}^{n} \beta_i + c_3 \prod_{i=1}^{n} \gamma_i \right) \right] \right\},
\]
(76)
each of them with multiplicity $2^{n-1}$. By Lemma 3, we note that minimizing $S_q(\Phi(\rho))$ is equivalent to maximizing
\[
\left| c_1 \prod_{i=1}^{N} \alpha_i + c_2 \prod_{i=1}^{N} \beta_i + c_3 \prod_{i=1}^{N} \gamma_i \right|,
\]
(77)
over all possible vectors $\{\tilde{\Pi}_i\}_{i=1}^{n}$.

To maximize Eq. (77), suppose that $\{\tilde{\Pi}_i\}_{i=1}^{n}$ are given; then Eq. (77) can be regarded as the size of the inner product of two vectors
\[
\left| (\alpha_n, \beta_n, \gamma_n) \cdot \left( c_1 \prod_{i=1}^{n-1} \alpha_i, c_2 \prod_{i=1}^{n-1} \beta_i, c_3 \prod_{i=1}^{n-1} \gamma_i \right) \right|.
\]
(78)
Because $(\alpha_n, \beta_n, \gamma_n)$ is a unit vector, Eq. (78) clearly obtains its maximum
\[
\left( c_1 \prod_{i=1}^{n-1} \alpha_i^2 + c_2 \prod_{i=1}^{n-1} \beta_i^2 + c_3 \prod_{i=1}^{n-1} \gamma_i^2 \right)^{1/2},
\]
(79)
that is, $(\alpha_n, \beta_n, \gamma_n)$ is in the same direction with $(c_1 \prod_{i=1}^{n-1} \alpha_i, c_2 \prod_{i=1}^{n-1} \beta_i, c_3 \prod_{i=1}^{n-1} \gamma_i)$.

Now suppose $\{\tilde{\Pi}_i\}_{i=1}^{n-2}$ are given. Because $(\alpha_{n-1}, \beta_{n-1}, \gamma_{n-1})$ is also a unit vector, simple calculus implies that Eq. (79) obtains its maximum as
\[
\left( \max \left\{ c_1 \prod_{i=1}^{n-2} \alpha_i^2, c_2 \prod_{i=1}^{n-2} \beta_i^2, c_3 \prod_{i=1}^{n-2} \gamma_i^2 \right\} \right)^{1/2}.
\]
(80)
Thus the maximum of Eq. (80) over all possible $\{\tilde{\Pi}_i\}_{i=1}^{n-2}$ is clearly
\[
c = \max\{|c_1|, |c_2|, |c_3|\}.
\]
(81)
In other words, $S_q(\Phi(\rho))$ is Eq. (73) can be minimized when $\Phi(\rho)$ has eigenvalues
\[
\left\{ \frac{1}{2^n} (1 \pm c) \right\},
\]
(82)
each of them has multiplicity $2^{n-1}$, that is,
\[
\min_{\Phi} S_q(\Phi(\rho)) = -2^{n-1} \left[ \left( \frac{1 + c}{2^n} \right)^q \ln_q \left( \frac{1 + c}{2^n} \right) \right] - 2^{n-1} \left[ \left( \frac{1 - c}{2^n} \right)^q \ln_q \left( \frac{1 - c}{2^n} \right) \right] = \frac{1 - 2^{n-1} \left( \frac{1+c}{2^n} \right)^q + \left( \frac{1-c}{2^n} \right)^q}{q - 1}.
\]
(83)
If $n$ is odd, Eq. (74) enables us to evaluate $S_q(\rho)$ in Eq. (73); thus together with Eq. (83), we have the $q$-GQD of $\rho$ in Eq. (70). For an even $n$, Eq. (75) together with Eq. (73) leads us to the $q$-GQD of $\rho$ in Eq. (71).

Due to the continuity of Tsallis entropy with respect to the parameter $q$, Theorems 4 and 5 recover the results in Ref. [12] as a case when $q = 1$. We also note that for the case when $c_1 = \alpha, c_2 = -\alpha, c_3 = 2\alpha - 1$, and $n = 2$, $\rho$ in Eq. (69) is reduced to a class of two-qubit states, the so-called $a$ state, introduced in Ref. [13]. We illustrate the difference of $q$-GQD for two $\alpha$ states (corresponding to $\alpha = 0.58$ and $\alpha = 0.3$) in Fig. 1.

This difference takes either negative or positive values depending on the range of $q$. In other words, $A$ relative order among quantum states in terms of correlation measures is not invariant, because it strongly depends on what entropy function is used to define the correlation measure.

V. MONOGAMY OF $q$-GQD IN MULTIPARTY QUANTUM SYSTEMS

In this section, we show that the restricted shareability of $q$-GQD in multiparty quantum system can be characterized

\[
\text{FIG. 1. (Color online) Difference between $q$-GQD of two $\alpha$ states for $\alpha = 0.58$ and $\alpha = 0.3$. The vertical axis represents the difference value of $q$-GQD whereas the horizontal axis represents the parameter $q$ for $0 < q < 1$.}
\]
as an inequality, thus \( q \)-GQD monogamy of multipartite quantum systems. By investigating possible decomposition of multipartite \( q \)-GQD into bipartite \( q \)-GQD’s among subsystems, we provide a sufficient condition for a monogamy inequality of \( q \)-GQD in multipartite quantum systems.

For a \( n \)-party quantum state \( \rho^A \), let us consider the difference of \( q \)-mutual information in Eq. (40) generated by a local von Neumann measurement \( \Phi = \{ \Pi_j = \Pi_{j_1}^{A_1} \otimes \Pi_{j_2}^{A_2} \otimes \cdots \otimes \Pi_{j_n}^{A_n} \} \),

\[
D_q^\Phi(\rho^A) = I_q(\rho^A) - I_q[\Phi(\rho^A)],
\]

which we refer to as the \( q \)-GQD of \( \rho^A \) induced by \( \Phi \).

In order to consider a possible decomposition of \( D_q^\Phi(\rho^{A_1 \cdots A_n}) \) in terms of bipartite \( q \)-GQDs among subsystems, we further define the \( q \)-GQD of subsystems concerned with the local von Neumann measurement \( \Phi \); for each \( k = 1, 2, \ldots, n - 1 \) and the \((k + 1)\)-party reduced density matrix \( \rho^{A_1 \cdots A_k A_{k+1}} \), we consider it as a bipartite quantum state \( \rho^{A_1 \cdots A_k A_{k+1}} \) with respect to the bipartition between \( A_1 \cdots A_k \) and \( A_{k+1} \). The \( q \)-mutual information of the bipartite state \( \rho^{A_1 \cdots A_k A_{k+1}} \) is then

\[
I_q(\rho^{A_1 \cdots A_k A_{k+1}}) = S_q(\rho^{A_1 \cdots A_k}) + S_q(\rho^{A_{k+1}}) - S_q(\rho^{A_1 \cdots A_k A_{k+1}}).
\]

We also have the \( q \)-mutual information of \( \rho^{A_1 \cdots A_k A_{k+1}} \) generated by \( \Phi \) as

\[
I_q[\Phi^{A_1 \cdots A_k A_{k+1}}(\rho^{A_1 \cdots A_k A_{k+1}})] = S_q(\Phi^{A_1 \cdots A_k}(\rho^{A_1 \cdots A_k})) + S_q(\Phi^{A_{k+1}}(\rho^{A_{k+1}})) - S_q(\Phi^{A_1 \cdots A_k A_{k+1}}(\rho^{A_1 \cdots A_k A_{k+1}})),
\]

where \( \Phi^{A_1 \cdots A_k A_{k+1}} = \{(\Pi_{j_1}^{A_1} \otimes \cdots \otimes \Pi_{j_k}^{A_k} \otimes \Pi_{j_{k+1}}^{A_{k+1}}) \} \) is the local von Neumann measurement on the first \( k \) + 1 subsystems induced from \( \Phi \) and \( \Phi^{A_1 \cdots A_k A_{k+1}}(\rho^{A_1 \cdots A_k A_{k+1}}) \) is the density matrix after the nonselective measurement of \( \Phi^{A_1 \cdots A_k A_{k+1}} \). For simplicity, we denote

\[
\Phi^{A_1 \cdots A_k A_{k+1}}(\rho^{A_1 \cdots A_k A_{k+1}}) = \Phi(\rho^{A_1 \cdots A_k A_{k+1}}),
\]

if there is no confusion. The \( q \)-GQD of the bipartite reduced density matrix \( \rho^{A_1 \cdots A_k A_{k+1}} \) generated by the local von Neumann measurement \( \Phi \) is then defined as

\[
D_q^\Phi(\rho^{A_1 \cdots A_k A_{k+1}}) = I_q[\Phi(\rho^{A_1 \cdots A_k A_{k+1}})] - I_q(\rho^{A_1 \cdots A_k A_{k+1}})
\]

for each \( k = 1, 2, \ldots, n - 1 \).

Now we have the following theorem about the decomposability of \( D_q^\Phi(\rho^{A_1 \cdots A_n}) \) in terms of bipartite \( q \)-GQDs among subsystems.

**Theorem 6.** For an \( n \)-party quantum state \( \rho^A = \rho^{A_1 \cdots A_n} \) and given a nonselective measurement \( \Phi = \{ \Pi_j = \Pi_{j_1}^{A_1} \otimes \Pi_{j_2}^{A_2} \otimes \cdots \otimes \Pi_{j_n}^{A_n} \} \), \( D_q^\Phi(\rho^{A_1 \cdots A_n}) \) can be decomposed as

\[
D_q^\Phi(\rho^{A_1 \cdots A_n}) = \sum_{k=1}^{n-1} D_q^\Phi(\rho^{A_1 \cdots A_k A_{k+1}}).
\]
Multiparty quantum systems.

VI. CONCLUSION

Using Tsallis-$q$ entropy, we have proposed a class of quantum correlation measures, $q$-GQD, and showed its non-negativity for $0 < q \leq 1$. We have also provided analytic expressions of $q$-GQD for multiqubit Werner-GHZ states and a class of three-parameter multiqubit states by investigating the monotonicity of Tsallis-$q$ entropy. We have further provided a sufficient condition for monogamy inequality of $q$-GQD in multipart quantum systems.

As a one-parameter class of correlation measure, $q$-GQD contains GQD as a special case when $q = 1$. Moreover, we have shown that the relative order among quantum states in terms of correlation measures strongly depends on what entropy function is used. In other words, the quantum correlations quantified by $q$-GQD are seen in different manners by distinct entropic quantifiers.

The class of $q$-GQD monogamy inequality provided here also encapsulates the known case of monogamy inequality in terms GQD as special cases [31], as well as their explicit relation with respect to the continuous parameter $q$. We believe our result provides a useful methodology to understand quantum correlations in multiparty quantum systems.
