We report on a comprehensive study of the transport, specific heat, magnetic susceptibility and optical spectroscopy on single crystal of Fe\textsubscript{1.05}Te. We confirm that Fe\textsubscript{1.05}Te undergoes a first-order phase transition near 65 K. However, its physical properties are considerably different from other parent compounds of FeAs-based systems, presumably attributed to the presence of excess Fe ions. The charge transport is rather incoherent above the transition, and no clear signature of the gap is observed below the transition temperature. Strong impurity scattering effect exists also in Se-doped superconducting sample Fe\textsubscript{1.03}Se\textsubscript{0.30}Te\textsubscript{0.70}, leading to a relatively low T\textsubscript{c} but a rather high upper critical field.

PACS numbers: 74.70.-b,74.25.Gz

The recent discovery of superconductivity in Fe- and Ni-based transition metal oxypnictides has triggered tremendous interest in searching for new Fe-based superconductors with similar PbO-type tetrahedral layers\textsuperscript{2,3,4}\(\alpha\)-Fe\textsubscript{2}Se\textsubscript{3}(Te) belongs to this tetragonal family with the simplest crystal structure. It comprises only a continuous stacking of tetrahedral FeSe(1\textsubscript{1}) layers along the c-axis. Superconductivity with transition temperature T\textsubscript{c} up to 15 K was obtained on Fe\textsubscript{1+\textit{x}}(Se\textsubscript{1-\textit{x}}Te\textsubscript{\textit{x}}) system at ambient pressure\textsuperscript{2,3,4,7,8}. The T\textsubscript{c} can go up to 27 K at a pressure of 1.48 GPa.\textsuperscript{2,3} First principle calculations\textsuperscript{5,6,7} on stoichiometric FeSe indicate that the electron-phonon coupling cannot explain the superconductivity at such a high transition temperature, and FeSe is in the category of unconventional superconductivity. The calculated Fermi surface (FS) structures of FeS, FeSe and FeTe are very similar to that of FeAs based superconductors, with cylindrical hole sections at the zone center and electron sections at the zone corner. Those Fermi surfaces are separated by a two-dimensional nesting wave vector at \((\pi, \pi)\). Spin-density-wave (SDW) ground state is obtained due to the substantial FS nesting effect. In particular, in going from FeSe to FeTe, the strength of the SDW instability is strongly enhanced.

Experimentally, it is difficult to synthesize the stoichiometric \(\alpha\)-Fe\textsubscript{2}Se\textsubscript{3}(Te), and excess Fe is always present in synthesized compounds\textsuperscript{2,3,4,7,8,9}. Those excess Fe ions occupy randomly on the Fe(2) sites as in Fe\textsubscript{2}As compound or the Li sites in LiFeAs compound (both have Cu\textsubscript{2}Sb type structure) at a low partial filling\textsuperscript{8,9,10,11}. The superconductivity was found to appear in wide range of compositions Fe\textsubscript{1+y}Se\textsubscript{1-x}Te\textsubscript{x}(0<\textit{x}<1)\textsuperscript{2,3,4,7,8,9} but the Se-free Fe\textsubscript{1+y}Te undergoes a structure distortion along with the establishment of a long range SDW order near 65K\textsuperscript{2,3,4,7,8,9}. This is consistent with the expectation of the first principle density functional calculation showing higher strength of SDW instability for FeTe.\textsuperscript{2} However, a complex incommensurate long range antiferromagnetic (AF) order is formed\textsuperscript{2} With the reduction of the excess Fe, the AF order tends to become commensurate, but the moments rotate 45 degrees relative to the moment direction found in other FeAs-based AF spin structures (along the orthorhombic long (a) axis).\textsuperscript{2,3,4,7,8,9} More recent density functional calculations\textsuperscript{11} indicate that the excess Fe is in a valence state near Fe\textsuperscript{3+} and therefore donates electron to the system. Furthermore, the excess Fe has a large magnetic moment and interacts with the magnetism of FeTe layers, resulting in a complex magnetic order.

Due to the interaction of the magnetic moment of excess Fe with the itinerant electrons of FeTe layer, we can expect that the electronic properties would be substantially affected as well. It is of great interest to investigate the electronic properties of this material and compare them with LaFeAsO and AFe\textsubscript{2}As\textsubscript{2} (A=Ba, Sr) systems. Here we report on a comprehensive study of the transport, specific heat, magnetic susceptibility and optical spectroscopy on single crystals of Fe\textsubscript{1.05}Te and Fe\textsubscript{1.03}Se\textsubscript{0.30}Te\textsubscript{0.70}. We confirm that Fe\textsubscript{1.05}Te undergoes a first-order phase transition near 65 K. Above T\textsubscript{SDW}, dc resistivity shows a semiconducting like behavior. In accord with this non-metallic property, the optical conductivity is rather flat with an absence of Drude component. This suggests that there is almost no well-defined quasiparticle with sufficiently long life time. The charge transport is rather incoherent. Below T\textsubscript{SDW}, a small Drude weight develops from the incoherent background. But unlike LaFeAsO and SrFe\textsubscript{2}As\textsubscript{2}, there is no clear sign of gap opening from optical, Hall coefficient and low-T specific heat measurement results. This is compatible with the disappearance of commensurate SDW caused by the size mismatch between the electron and hole Fermi surfaces induced by excess Fe as suggested by recent density functional calculations\textsuperscript{11}. The present work provides strong evidence that the excess Fe moments strongly scatter the charge carriers in FeAs layers. The superconducting properties of a Fe\textsubscript{1.03}Se\textsubscript{0.30}Te\textsubscript{0.70} single crystal are also investigated. A surprisingly high upper critical field is observed, again yielding evidence for strong impurity scattering effect in the superconducting sample.

Large single crystals of Fe\textsubscript{1.05}Te and Fe\textsubscript{1.03}Se\textsubscript{0.30}Te\textsubscript{0.70} have been grown by the Bridgeman technique. The starting compositions were selected as FeTe and FeSe\textsubscript{0.30}Te\textsubscript{0.70}, respectively. The mixtures of Fe, Te(Se) were grounded thoroughly and sealed in an evacuated
quartz tube. The tube was heated to 920 °C and cooled slowly to grow single crystals. The obtained crystals were checked by X-ray diffraction (XRD) and their compositions were determined by Inductively Coupled Plasma (ICP) analysis. The optical reflectance measurements were performed down to 1.8 K in a Physical Property Measurement System (PPMS) of Quantum Design Company. The optical reflectance measurements were performed on a Bruker IFS 66/s spectrometer on newly cleaved surfaces (ab-plane) of those crystals up to 25000 cm$^{-1}$. An in situ gold and aluminium overcoating technique was used to get the reflectivity R(ω). The real part of conductivity $\sigma_1(\omega)$ is obtained by the Kramers-Kronig transformation of R(ω).

Figure 1(a) shows the temperature dependence of in-plane resistivity $\rho_{ab}$ of Fe$_{1.05}$Te in zero field and 14 T (magnetic field along the c-axis). At high temperature, the resistivity shows a semiconducting-like behavior, i.e., $\rho_{ab}$ increases slowly with decreasing temperature, whereas $\rho_{ab}$ drops steeply below 65 K and then behaves quite metallic. This discontinuous change in the resistivity at 65 K is due to a structural phase transition, accompanied by magnetic transition. A thermal hysteresis of 2 K is clearly observed in the resistivity data shown in an inset to Fig.1(a). This is consistent with the recent neutron diffraction measurements on Fe$_{1+y}$Te polycrystalline samples, which indicated that the P4/mmm tetragonal structure distorts to a Pmnn orthorhombic or a $P2_1/m$ monoclinic structure and Fe$_{1.05}$Te orders into an incommensurate magnetic state when the temperature is lowered below ~65 K. We have also attempted to probe the influence of magnetic fields on the $\rho(T)$ behavior. We find that the magnetic transition temperature is insensitive to the applied field and the magnetoresistance is negligibly small in the AF state (less than 0.5% near 2 K at the maximum applied field of 14 T). This behavior is different from that observed in SrFe$_2$As$_2$, $\rho_{ab}(8T)/\rho_{ab}(0T)$ reaching as high as 20% at 10 K. This indicates that the magnetic coupling is much stronger in FeTe compared to other FeAs-based systems.

In Fig. 1(b), we present the temperature dependence of magnetic susceptibility $\chi$ in a field of 1 T with H||ab and H||c-axis, respectively. Near 65 K, $\chi$ decreases abruptly by a factor of two, indicative of the presence of first-order phase transition. Above this temperature, $\chi$ shows a Curie-Weiss like behavior. This is in contrast to those observed in RFeAsO (R=La and rare earth elements) and AFe$_2$As$_2$ (A=Sr, Ba) parent compounds above $T_{SDW}$[12,13] The Curie-Weiss like behavior could be naturally attributed to local moment formation of the excess Fe.

To get more information about the magnetic and structural phase transition, we preformed specific heat measurement for Fe$_{1.05}$Te. Figure 2(a) shows the temperature dependence of specific heat $C_p$ from 2 to 90 K. We can see clearly a sharp $\delta$-function shape peak at about 65 K with $\Delta C \sim 0.8$ J/molK. This is a characteristic feature of a first-order phase transition; even though the relaxation method employed in PPMS to measure heat capacity suppresses sharp features due to first-order transitions. The transition temperature agrees well with that observed in resistivity and magnetic susceptibility measurements. It is worth noting that only one peak at around 65 K is observed in Fe$_{1.05}$Te. This suggests the structural transition and magnetic order occur at the same temperature. At low temperatures, a good linear $T^2$ dependence of $C_p/T$ is observed, indicating that the specific heat $C_p$ is mainly contributed by electrons and phonons (see inset of Fig. 2(a)). The fit yields the electronic coefficient $\gamma=34$ mJ/molK$^2$, and the Debye temperature $\theta_D=141$ K. The electronic coefficient is significantly larger than the values obtained from the band structure calculations[14]. Note that, for the parent compound of LaFeAsO and SrFe$_2$As$_2$, the electronic coefficients are significantly smaller than the values obtained from the band structure calculations for non-magnetic state. It was explained as due to a partial energy gap opening below SDW transition which removes parts of the density of states[12,15]. Thus, the higher value here suggests an absence of gap opening below the transition.
It is important to note that the conductivity spectra at different temperatures. In accord with the semiconductor-like T-dependent dc resistivity above $T_{SDW}$, we find that the low frequency reflectance decreases slightly with decreasing temperature from 300 to 70 K, leading to a reduction of low-$\omega$ conductivity. It is important to note that the conductivity spectra above $T_{SDW}$ are rather flat. Definitely, it is not a semiconductor as $\sigma_1(\omega)$ does not indicate a presence of any semiconductor-like gap, but it is not a usual metal as well because of the absence of a Drude-like peak. As is well known, the width of Drude peak is linked with the scattering rate (or inverse of the transport lifetime) of the quasiparticle, the measurement result indicates that there is no well defined quasiparticle with sufficiently long transport life time above $T_{SDW}$. The charge transport is rather incoherent. Below $T_{SDW}$, the low-$\omega$ $R(\omega)$ increases fast. Correspondingly, a Drude component in $\sigma_1(\omega)$ develops quickly from the incoherent background. However, unlike the parent compounds of LaFeAsO and $AFe_2As_2$ ($A=\text{Ba}, \text{Sr}$), there is no partial gap formation in optical spectra below $T_{SDW}$, which is consistent with the specific heat and Hall coefficient data mentioned above.

All above experiment results indicate that the $\text{Fe}_{1.05}\text{Te}$ compound is very different from the $\text{LaFeAsO}$ and $AFe_2As_2$ ($A=\text{Ba}, \text{Sr}$) parent compounds. In $\text{LaFeAsO}$ and $AFe_2As_2$ ($A=\text{Ba}, \text{Sr}$), the charge carriers are itinerant, the SDW order is driven by the nesting of FS, which also leads to a partial energy gap formation and a removal of a large part of conducting carriers. However, in $\text{Fe}_{1.05}\text{Te}$, no well-defined quasiparticles with sufficiently long life time exist above $T_{SDW}$, very likely due to strong magnetic scattering from the excess Fe ions, and furthermore, no clear gap formation is seen below $T_{SDW}$. Those behaviors might be understood from a local moment picture with a complex frustrations but a recent density functional calculations based on itinerant framework indicate that the doping effect and the large magnetic moment induced by excess Fe could cause a size mismatch between the electron and hole Fermi surfaces and a disappearance of commensurate SDW order. The cooperative effect of excess Fe and the electrons in the FeTe layers may give such complicated behavior although the driving force is the FS nesting tendency which is particularly strong in $\text{FeTe}_{1.05}$. 

**FIG. 3:** (Color online) Optical reflectance (a) and conductivity (b) spectra at different temperatures for $\text{Fe}_{1.05}\text{Te}$.

**FIG. 4:** (Color online) (a) Temperature dependence of the in-plane electrical resistivity for $\text{Fe}_{1.03}\text{Se}_{0.30}\text{Te}_{0.70}$ at zero field. Inset: Temperature dependence of Hall coefficient for $\text{Fe}_{1.03}\text{Se}_{0.30}\text{Te}_{0.70}$. (b) and (c) Temperature dependence of the in-plane electrical resistivity for $\text{Fe}_{1.03}\text{Se}_{0.30}\text{Te}_{0.70}$ in low temperature region at fixed fields up to 14T for H $\parallel ab$ plane and H $\parallel c$-axis, respectively. (d) $H_{SDW}(T)$ plot for H $\parallel ab$ plane (closed square) and H $\parallel c$-axis (closed circle), respectively.
Finally we present the physical properties of a superconducting single crystal Fe$_{1.03}$Se$_{0.30}$Te$_{0.70}$. In such Se doped sample, the magnetism/structure instability is suppressed and superconductivity appears instead. Figure 4(a) shows the temperature dependence of resistivity $\rho_{ab}$ on the single crystal Fe$_{1.03}$Se$_{0.30}$Te$_{0.70}$ with I[ab] at zero field. $\rho_{ab}$ increases with decreasing T and shows a sharp drop to zero at about 11 K, indicating a superconducting transition. The Hall coefficient $R_H$, as shown in the inset of Fig. 4(a), is positive, suggesting dominantly hole-type conducting carriers. Figure 4(b) and Figure 4(c) show $\rho_{ab}(T)$ for Fe$_{1.03}$Se$_{0.30}$Te$_{0.70}$ in external magnetic fields up to 14 T within ab plane and along c-axis, respectively. We can see the superconducting transition is broadened slightly in magnetic fields up to 14 T. The behavior is rather different from polycrystalline LaFeAs where the superconducting transition is broadened strongly in magnetic fields. Figure 4(d) shows $H_{c2}$-T$_c$ curves for both H||ab and H||c, respectively, where T$_c$ is defined by a criterion of 50% of normal state resistivity. The curves $H_{c2}(T)$ are very steep with slopes $dH_{c2}/dT|_{T_c}=5.96$ T/K for H||ab and $dH_{c2}/dT|_{T_c}=3.69$ T/K for H||c. Using the Werthamer-Helfand-Hohenberg formula $H_{c2}(0)=-0.69(dH_{c2}/dT|_{T_c})$ and taking T$_c=12.4$ K, the upper critical fields are estimated as $H_{c2}^a=51$ T and $H_{c2}^c=31$ T, respectively. It is important to note that those values are very large, comparable to the values found for F-doped LaFeAsO with $T_c$ higher than 20 K.

It has been well known that, for the two-gap superconductor, where the $H_{c2}$ increases remarkably with the increase of resistivity by alloying MgB$_2$ with non-magnetic impurities. Then, the very high $H_{c2}$ observed in Fe$_{1.03}$Se$_{0.30}$Te$_{0.70}$ could be reasonably attributed to the strong impurity scattering effect from the randomly distributed excess Fe in such a new multiple band superconductor. The impurity scattering, particularly in the case of Fe$^+$ with a magnetic moment, would also suppresses $T_c$. This could be the reason why $T_c$ is not so high, although density functional calculations indicated a higher strength of SDW order in stoichiometric FeTe, and therefore expected a higher $T_c$ after the suppression of SDW order.

To conclude, the electronic properties of single-crystalline Fe$_{1.05}$Te and Fe$_{1.03}$Se$_{0.30}$Te$_{0.70}$ were studied. The excess Fe ions in those compounds dramatically modify their properties. For Fe$_{1.05}$Te above $T_{SDW}$, we could not identify well-defined quasiparticles with sufficiently long life time. The charge transport is rather incoherent. Below $T_{SDW}$, a small Drude weight develops from the incoherent background. But unlike LaFeAsO and SrFe$_2$As$_2$, there is no clear sign of gap opening from optical, Hall coefficient and low-T specific heat measurement results. Strong impurity scattering effect seems to exist also in Se-doped superconducting sample, which leads to a relatively low $T_c$ but a rather high upper critical field in such a new multiple band superconductor.
