Abstract
This paper proposed a new trajectory tracking control method based on non-time motion reference for non-holonomic mobile robots. Different from the traditional time-based control theory, this method determines the reference points through the geometrical relationship between the current position and the desired path. Substituting them into the time based motion controller, a non-time based motion controller can be derived. Since the reference points are only related to the current state of the robot, the method proposed gets rid of the influence by time, thereby avoiding the disadvantages of loss of tracking ability when the mobile robot encounters undesired incidents such as motor shutdown or tire skids. Finally, the feasibility of this method is verified through numerical simulations of typical path tracking.

Keywords
Mobile robot, Non-time based motion controller, Reference point, Trajectory tracking

Introduction
A wheeled mobile robot is one kind of typical system with non-holonomic constraints [1], and has been paid much attention because of the difficulties and challenges on its path tracking control issue. Solving it, many scholars consider desired paths as functions with respect to time, and study on the path tracking control problem in time-domain. Dynamic state feedback linearization method [2,3] and non-linear control method based on Lyapunov [4-6] are the two classical control methods. The tracking problems of them are solved in time-domain, therefore the resulting tracking errors and control laws are time-dependent. Facing the situation of tire skids, obstacles or motor shutdown, it may occur that the tracking errors of the mobile robot abruptly change or increase with time under the control of these methods. This may degrade the tracking effect of the mobile robot, and moreover lead to the loss of the ability to track the ideal path in some extreme circumstances.

What causes the problem above is that the determination of the reference point is only related to time but not to the current states of the robot, which leads to the incompatibility of motion planning and actual control. To overcome the shortcomings of the above means, predictive control methods [7,8] and fuzzy control [9,10] methods and others...
[11-13] have been carried out. In these methods, although different ways are proposed to deal with the tire skids, obstacles or motor shutdown, they still use the time as the variable to design the controller. Thus, they still have some disadvantages, such as slow reaction time or too complex controller structure. Different from the above method, Wei [14] proposed a non-time based controller designed by the reference variables of time-independent state variables, such as arc length or projection of the coordinate axes of the current position, and used STR (state to reference) mapping to convert time reference controller to non-time based controller. The article points out that the stability of a non-time based controller is determined by the stability of time reference controller, and the relevant proof is derived. Overcoming the shortcomings of time reference control law to some extent, this method is still complicated to be realized, and the STR mapping is hard to find. Similar to the design concept of Wei’s controller, Wang [15] considered the $x$-axis projection of the position of the robot as the reference variable, and designed a path tracking controller according to Lyapunov stability method. Although the effectiveness was verified by simulations, this control method existed the problem of singularity and in-continuity. The main reasons for the existing problems of the two methods mentioned above are that the non-time reference variables selected in the controller design process do not own the characteristic of monotone increment and that the curve is a one-one mapping of a reference variable, which reference time $t$ has. In another word, it is difficult to find a non-time reference variable having all the advantages that time reference variable $t$ has.

Since there is not a perfect non-time reference variable for controller design, then is there another way to design the non-time reference controller? In 1992, Coulter [16] applied the pure pursuit algorithm into the research of the path tracking method of the mobile robot and discussed the implementation of it, which is a non-time reference control method. Snider made a comparative study on the pure pursuit, Stanley method, error-based kinematics trackers and linear quadratic dynamic controllers in 2009, and showed that pure pursuit had a better performance than other controllers under conditions of random excitation and discontinuous paths. The concept of pure pursuit was widely used in the studies of path tracking control problems afterward [17-22], and received the good achievement. However, there are still some deficiencies in the pure pursuit method. Pure pursuit method searches for the target point through a constant lookahead distance, which will lead to the problems such as unable to find the target point, or to track the large curvature path with high precision. Moreover, as a lateral control method, the pure pursuit controller cannot adjust the longitudinal velocity, which limits the control effectiveness.

From the explanation above, it can be seen that there are still some insufficiencies in the two major non-time reference control methods, but core ideas of these two methods still make sense of the study on non-time reference control. Based on the two non-time reference algorithms mentioned above, this paper carried out a new non-time reference path tracking control method. Different from the means to obtain non-time reference point through STR mapping introduced by Wei [14], this paper draws on the advantage of the pure pursuit method [16], as well as uses geometric means to obtain control reference points and tracking control errors, and finally substitute them into time reference controller to realize the conversion to non-time reference controller. Simulations of several typical routes are carried out, and the results of which verifies the effectiveness of the method of this paper.

This paper is organized as follows: Section 4 introduces the model of differential drive wheeled robot; the design process of the controller is presented in Section 5; in Section 6, simulations on path tracking of circles and sinusoid are carried out to verify the effectiveness and feasibility of the method introduced in this paper; and Section 7 shows the conclusions of this paper.

**Model of Mobile Robot System**

The research object of this paper is a differential wheeled mobile robot, and structural model of which are depicted in Figure 1. In Figure 1, $C$ is the central point of the axis of the two driving wheels, namely the central point of the robot, and $d$ is the distance between the two driving wheels. The kinematic equation of the central point of the robot can be expressed as

\[
\begin{align*}
    x &= v \cos \theta \\
    y &= v \sin \theta \\
    \dot{\theta} &= \omega
\end{align*}
\]  

(1)
advantages of the non-time based variable radically, it brings some new problems, such as the control oscillation that appears when there is a sudden change in the curvature of the tracking curve, which is caused by the neglect of the position relationship between the current robot position and the tracking trajectory. In addition, the pure pursuit is actually a lateral control method, and cannot adjust the longitudinal velocity of the mobile, which lower the effectiveness of the controller to some extent.

A new non-time based control method is proposed in this paper, combining the merits of the two methods above. In this method, it is prior to design a time based controller, then geometric means are taken to obtain the trajectory reference point and calculate the tracking error, and finally a non-time based controller can be derived by replacing the tracking error based time with the geometric tracking error. The detail design process of the controller is described as follows.

**Time based controller**

As shown in Figure 2, in current time, the reference attitude of the mobile robot on the desired trajectory is defined as \( P_e=[x_c, y_c, z_c]^T \), the reference velocity is \( q_e=[v_e, \omega_e]^T \), and the current position of the robot is \( P_r=[x_r, y_r, z_r]^T \). In the inertial coordinate system, the attitude error of the robot is

\[
P_e = P_r - P_e = \begin{bmatrix} x_r - x_c \\ y_r - y_c \\ \theta_r - \theta_c \end{bmatrix}
\]

The projection of the attitude error on the robot

body-fixed is [4]
\[
\begin{bmatrix}
    e_x \\
    e_y \\
    e_\theta
\end{bmatrix} =
\begin{bmatrix}
    \cos \theta & \sin \theta & 0 \\
    -\sin \theta & \cos \theta & 0 \\
    0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
    p_x \\
    p_y \\
    p_\theta
\end{bmatrix}
\]
(4)

Derived with respect to time, the above equation can be derived into [3]
\[
\begin{bmatrix}
    \dot{e}_x \\
    \dot{e}_y \\
    \dot{e}_\theta
\end{bmatrix} =
\begin{bmatrix}
    e_y - v_x e_\theta + v_x \cos e_\theta \\
    -e_x - v_y e_\theta + v_y \sin e_\theta \\
    -\omega_\theta - \omega
\end{bmatrix}
\]
(5)

Where, \(v\), \(\omega\) and \(\omega_\theta\) are the reference translational velocity, reference angular velocity respectively. According to Lyapunov stability method, the controller of the mobile robot can be obtained as [3]
\[
\begin{bmatrix}
    q_x \\
    q_y \\
    q_\theta
\end{bmatrix} =
\begin{bmatrix}
    v_x \cos e_\theta + K_e e_x \\
    \omega_\theta + v_y(K_x e_x + K_\theta \sin e_\theta) \\
    \omega
\end{bmatrix}
\]
(6)

Consider the limitation of maximum translational velocity \(v_{\text{max}}\) and maximum angular velocity \(\omega_{\text{max}}\) of the actual robot motion, the amplitude of the controller can be limited as
\[
v = \min(v, v_{\text{max}}) \quad \omega = \text{sign}(\omega) \cdot \min(|\omega|, |\omega_{\text{max}}|)
\]
(7)

**Selection of the reference point**

The process to search for a control target point through a geometric relationship is given in the following. As could be seen in Figure 2, the desired path equation is \(y = f(x)\), \(P_c = [x_c, y_c, \theta_c]^T\) is the current configuration of the vehicle, square of the distance from \(P_c\) to an arbitrary point \(P_a = [x, y, \theta]^T\) on the desired path could be calculated as \(L^2(x) = (x_c - x)^2 + (y_c - y)^2\). Let the minimum distance between \(P_c\) and \(P_a\) is \(d_{\text{min}}\). At this situation, \(P_a\) is called the target point and denoted by \(P_{r1}\). Since \(P_{r1}\) is the closest point to \(P_a\), \(x_{r1}\) is an extreme point of \(L^2(x)\), and \(P_{r1}\) meets
\[
\left\{ \begin{align*}
    L^2(x_{r1}) &= -2(x_c - x_{r1}) - 2(y_c - y_{r1})y'_{r1} = 0 \\
    y_{r1} &= f(x_{r1})
\end{align*} \right.
\]
(8)

By solving the above equation, we can get the values of \(x_{r1}\) and \(y_{r1}\).

In the method discussed in this paper, besides \(P_{r1}\) is selected as a reference point of non-time based motion control, the ending point \(P_{r2}\) of the intercept segment from \(P_{r1}\) along the forward direction of the reference trajectory with the intercept length \(l_{in}\) is also selected as a reference point of non-time based motion control. The intercept length \(l_{in}\) can take on any value, which is like as the lookahead distance in the pure pursuit method [13]. When \(l_{in} = 0\), \(P_{r2} = P_{r1}\). The calculation process of the circular trajectories and arbitrary trajectories are given as follow.

**Circular trajectories tracking**

As shown in Figure 3, let the equation of the circular trajectory to be tracked is \((x - x_1)^2 + (y - y_1)^2 = r^2\). Point \(P_0(x_0, y_0)\), the center of the circular trajectory, and the current position of the mobile robot is \(P_c = [x_c, y_c, \theta_c]^T\). The closest point \(P_{r1}\) from the point \(P_c\) to the circular trajectory is the cross point of that trajectory and the line segment \(P_0P_c\). Let the angle between the positive direction of x axis and the line segment \(P_0P_{r1}\) is \(\alpha\), and the position and attitude of reference point \(P_{r2}\) can be expressed as
\[
\begin{align*}
    x_{r2} &= x + r \cos \alpha \\
    y_{r2} &= y + r \sin \alpha \\
    \theta_{r2} &= \pi/2 + \alpha
\end{align*}
\]
(9)

The reference point \(P_{r2}\) can be found along the circular trajectory with the intercept length \(l_{in}\), and let the angle opposite to the arc between \(P_{r2}\) and \(P_{r1}\) to be \(\Delta \alpha\), with
\[
\Delta \alpha = \frac{l_{in}}{r}
\]
(10)

And the position and attitude of reference point \(P_{r2}\) is
\[ \begin{align*}
    x_{r2} &= x + r \cos(\alpha + \Delta \alpha) \\
    y_{r2} &= y + r \sin(\alpha + \Delta \alpha) \\
    \theta_{r2} &= \pi/2 + \alpha + \Delta \alpha
\end{align*} \tag{11} \]

**Arbitrary trajectories tracking**

As could be seen in Figure 4, let the trajectory function of an arbitrary continuous curve to be \( y = f(x) \), and according to equation (8), the reference point \( P_{r1} \) satisfies the equation as

\[ f'(x_1) \left[ y - f(x_1) \right] + (x_r - x_1) = 0 \tag{12} \]

The equation above is commonly nonlinear, and the least square iteration method is used to solve it. The coordinates corresponding to \( P_{r1} \) is

\[ P_{r1} = \left[ x_{r1}, f(x_{r1}), \arctan 2(x_{r1}, f(x_{r1})) \right]^T \tag{13} \]

It is not guaranteed that an arbitrary continuous curve must be an elementary integrable curve, so

![Figure 4: Reference point of continuous curve trajectory.](image)

![Figure 5: Tracking a circle curve with different initial error (Reference Point is \( P_{r1} \)).](image)
the coordinates of $P_2$ cannot be calculated from the intercept length $l_i$ of the curve by analytic calculation. Numerical integration method is used in this paper to obtain the coordinates of $P_2$.

**Numerical Simulation**

To verify the effectiveness of the control method proposed in this paper, numerical simulations of the circles and sinusoids trajectory tracking of the mobile robot are carried out in MATLAB.

In the simulations of circular trajectory, the trajectory equation is $x^2 + y^2 = 16$, and the mobile robot starts from three different initial positions, $P_1 = [1, -1, 0]^T$, $P_2 = [1, -2, \pi/6]^T$ and $P_3 = [2, -2, \pi/3]^T$, to track the circular trajectory under control. In the simulations of sine curve tracking, the trajectory equation of the tracked sinusoids is $y = \sin(x + \pi/2)$, the mobile robot is also started from the three initial positions that are $P_1 = [0, -1, 0]^T$, $P_2 = [0, 0.5, \pi/6]^T$ and $P_3 = [0, -1, \pi/3]^T$. In the above simulations, the desired translational velocity of the robot is $v_r = 1$ m/s, the maximum translational velocity is $v_{max} = 2$ m/s, the maximum angular velocity is $\omega_{max} = 1$ rad/s, and the control parameters are $K_x = 4$, $K_y = 5$, $K_\theta = 5$.

The result of the simulations is depicted in Figure 5, Figure 6, Figure 7 and Figure 8. It can be seen that the coordinates of $P_{r2}$ cannot be calculated from the intercept length $l_i$ of the curve by analytic calculation. Numerical integration method is used in this paper to obtain the coordinates of $P_{r2}$.

**Figure 6:** Tracking a circle curve with different initial error (Reference Point is $P_{r2}$).
from the simulation results that the control method proposed in this paper could achieve a good effect on all the two kinds of trajectories. Compared the calculating results of the two kinds of reference points, it can be seen that the first kind of reference points \( P_{r1} \) enables the mobile robot track on the target curves faster, and the tracking process is more smooth.

Figure 7: Tracking a sine curve with different initial error (Reference Point is \( P_{r1} \)).
If the length of forward direction interception $l_{in}$ is considered as a variable, the reference point $P_{r_{1}}$ can be regarded as on extreme condition when $l_{in} = 0$. Selecting $0, d_{min}/2$ and $d_{min}$ as the intercept length $l_{in}$ and substituting the obtained reference points into the tracking control simulations of trajectories of circle curve and sine curve, the results are shown in Figure 9 and Figure 10. The simulation results show that forward direction interception length of reference trajectories have an evident influence on the control effects. The time and distance taken to track the desired trajectory and the smoothness of trajectory interception length on the control effects.
the trajectory passed by the mobile robot are all inversely proportional to the length of forward direction interception, and the control output is proportional to the length. This means that the length of forward direction interception can be considered as a control parameter, and we can adjust the length according to the different demands to achieve the control goals.

From the above results, it can be got that the proposed method is effective when the environment is ideal. Next, two simulations will be performed to demonstrate the effectiveness of the proposal for dynamic obstacle and tire skidding, in which the robot will be controlled to track a circle.
The control parameters is the same as the above simulations. The results are plotted in Figure 11 and Figure 12. Observing Figure 11b, it can be found that during 15s-20s, the robot velocity is 0, which means the robot encounters a dynamic obstacle that goes away at 20 s. As can be seen from Figure 11a, it can be got that the robot controlled by the proposed method can track the desired path, but the time-based method in [3] can not. Observing Figure 12b, t can be found that during 13s-27s, the robot velocity is smaller than 0.2, which means the robot encounters tire skidding. As can be seen from
The method [3] needs to time as a reference variable. In this method, the tracking control is only related to the actual condition of the robot, not to time. As a result, it is more general and applicable. Numerical simulations not only verify the effectiveness of the method, but also indicate that the forward direction interception length can be considered as the adjustable parameter of the controller, and the control effects can be adjusted by varying the length. Though the good effectiveness of the method to track simple curves as well as complex curves has been proved by the simulations, it is still a pity that we have not carry out the proof of the effectiveness of the controller through theoretical derivation. We are hoping to research more deeply on the method through theoretical means to give a more rigorous proof.

**Conclusion**

For overcoming the shortcomings of the time-based trajectory tracking control methods, this paper proposed a control method based on non-time-based motion control concept. This method uses geometric criteria to select reference point, avoiding the disadvantages of time-based controllers very well, as well as the insufficiency of the controllers designed by non-time-based reference variables. In this method, the tracking control is only related to the actual condition of the robot, not to time. As a result, it is more general and applicable. Numerical simulations not only verify the effectiveness of the method, but also indicate that the forward direction interception length can be considered as the adjustable parameter of the controller, and the control effects can be adjusted by varying the length. Though the good effectiveness of the method to track simple curves as well as complex curves has been proved by the simulations, it is still a pity that we have not carry out the proof of the effectiveness of the controller through theoretical derivation. We are hoping to research more deeply on the method through theoretical means to give a more rigorous proof.
