Abstract
In this paper we study the equilibrium statistical mechanical as well as the dynamical properties of a Sherrington–Kirkpatrick model in a multi-bath setting introduced in Cugliandolo and Kurchan (1999 Physica A 263 242–51). We show that the free energy per particle in the thermodynamical limit obeys a variational principle of Parisi type. The relation between the resulting order parameters is discussed.

Keywords: spin glasses, Sherrington–Kirkpatrick model, multi-bath equilibrium

(Some figures may appear in colour only in the online journal)

1. Introduction

The equilibrium statistical mechanics of a disordered system (in general a system where the degrees of freedom can be divided in two different families) is described with two extreme prescriptions known, in the literature, as quenched and annealed. The spin-glass case, for instance, is defined by the quenched measure where the random coupling disorder \( J \) is kept fixed while the spins \( \sigma \) are thermalised according to the Boltzmann distribution. This perspective is considered physically relevant because the relaxation time of the disorder interaction variables is much slower than the one for the spin variables. Conversely, in the annealed prescription the disorder variables thermalise together with the spin ones. However one can also consider a different equilibrium measure depending on a real positive number \( \zeta \) with thermodynamic pressure

³ Author to whom any correspondence should be addressed.
\[ P(\zeta) = \frac{1}{\zeta} \log \mathbb{E}Z_J^\zeta, \tag{1} \]

where \( Z_J = \sum_\sigma e^{-\beta H(\sigma)} \) is the partition function given \( J \), a random variable depending on the disorder \( J \) obtained integrating on the spins. By definition we have that \( P(0) \) corresponds to the quenched equilibrium while \( P(1) \) to the annealed one. Hence \( \zeta \) can be viewed as a scale parameter in the unit interval interpolating between the quenched case and the annealed one [2]. The origins of (1) are to be found on the replica approach to spin glasses [15] where \( \zeta \) is at the outset an integer. Almost thirty years ago Kondor [13] calculated (1) using the replica trick for the partition function of the Sherrington–Kirkpatrick model. He found that the computation is essentially the usual one for a Parisi ansatz \( x(q) \), but with \( \zeta \leq x \leq 1 \). This does not mean that the solution itself is the usual \( x(q) \) truncated at \( x = \zeta \), but rather that the Parisi equations have to be solved in this interval. A rigorous proof of this result has obtained by Talagrand in [22].

In this work we consider a generalization of (1) consisting of a multi-scale equilibrium measure obtained by successive independent integration on a suitable class of variables. The idea of studying a system at different energy scales is common in physics since the pioneering works of Schwinger, Tomonaga, Feynman, Dyson in their treatment of QED or more explicitly in Wilson’s renormalisation group. From the mathematical physics point it goes back to the Euclidean approach to renormalisation group in quantum field theory (see [10, 20]). For two scales \( \zeta_0 \) and \( \zeta_1 \) the model is defined in terms of an interaction \( J = (J_0, J_1) \) with independent components:

\[ e^{\zeta_0 P(0)} = \mathbb{E}_0 Z_J^{\zeta_1}, \tag{2} \]

and

\[ e^{\zeta_0 P} = \mathbb{E}_0 e^{\zeta_0 P(0)}. \tag{3} \]

For \( r \) scales \( \zeta_0 < \zeta_1 < \ldots < \zeta_{r-1} < \zeta_r = 1 \) the recursion relations are

\[ e^{\zeta_l P^{(-1)}} = \mathbb{E}_l e^{\zeta_l P^{(-1)}}, \tag{4} \]

where \( 0 \leq l \leq r, \mathbb{E}_l e^{\zeta_l P^{(-1)}} = Z_J \) and \( P = P^{(-1)} \).

The relation (4) is also referred to as multi-bath in [4, 5] where it was applied to a class of out-of-equilibrium dynamical systems in the limit of small entropy production. Those papers presented analytical and numerical evidence suggesting that one can introduce several effective temperatures and partial thermalizations derived from the functional form (4) such that correlation and response functions behave as in a multiple equilibrium bath. In [14] the functional form (1) is used to get information about the landscape of the free energy of a given statistical mechanics model. More precisely, for a model with Hamiltonian \( H(\sigma) \), the idea is to introduce an auxiliary field \( \phi \) weakly pinned with \( \sigma \) but frozen. Keeping fixed the field \( \phi \), the variables \( \sigma \) thermalize in the usual Gibbs setting at inverse temperature \( \beta \). Then the resulting free energy is used as an effective Hamiltonian function acting on the field \( \phi \) at temperature \( \zeta \).

The examples given in [14] show how the previous construction can detect hidden metastable states of a glassy system.

An important observation is that under quite general assumptions on the randomness it is possible to express the relation (4) by coupling a suitable Hamiltonian function with a Ruelle probability cascade (RPC) [3, 8, 16, 21]). This structure is the core of the Guerra’s replica symmetry broken bound [11] for the SK model where a random field, described by a linear covariance, is coupled to a RPC.
In this work instead we consider and exactly solve a disordered mean field model where the Hamiltonian includes an SK term (two-spin interaction) and is coupled with a given RPC. From the physical point of view the effect of coupling a disordered Hamiltonian with a RPC corresponds to replacing the standard Gibbs equilibrium measure with a multi-bath thermalisation defined through a hierarchical sequences of averages (4) tuned by several effective ‘temperatures’. In section 19 we introduce the model and presents its solution. It turns out that the thermodynamical limit of the free energy can be expressed as a Parisi-like variational problem. In section 3 we give a dynamical interpretation of the multibath equilibrium and discuss some aspect of the solution we found.

2. The model and the solution

Given $N \geq 1$ let us consider a system of $N$ spins $\sigma = (\sigma_i)_{i \leq N} \in \Sigma_N = \{-1, 1\}^N$. Fix an integer $r \geq 1$ and two sequences $0 = \zeta_0 < \zeta_1 < \ldots < \zeta_r = 1$ (5) and $0 = \gamma_0 < \gamma_1 < \ldots < \gamma_r = 1$. (6)

For any $l = 1, \ldots, r$ consider an independent random Hamiltonian function

$$H_N(\sigma, l) = -\sqrt{\gamma_l^2 - \gamma_{l-1}^2} \sum_{i,j=1}^{N} J^{(l)}_{ij} \sigma_i \sigma_j - h \sum_{i=1}^{N} \sigma_i$$

where $J^{(l)}_{ij}$ is family of independent centered Gaussians with variance $\gamma_l^2 - \gamma_{l-1}^2$ and $h \in \mathbb{R}$ is a given external magnetic field. The family $H_N(\sigma, l)$ is a gaussian process on $(\sigma, l) \in \Sigma_N \times \{1, \ldots, r\}$ with covariance

$$\mathbb{E}[H_N(\sigma^1, l)H_N(\sigma^2, l)] = N \left( \sqrt{\gamma_l^2 - \gamma_{l-1}^2} q_N(\sigma^1, \sigma^2) \right)^2$$

where

$$q_N(\sigma^1, \sigma^2) = \frac{1}{N} \sum_{i=1}^{N} \sigma_i^1 \sigma_i^2$$

is the usual overlap. Then we define the pressure density as

$$p_N = \frac{1}{N} \log Z_{0,N}$$

where $Z_{0,N}$ is obtained recursively in the following the general scheme in (4). We denote by $\mathbb{E}_l$ the average w.r.t. the randomness in $H_N(\sigma, l + 1)$ and starting from

$$Z_{r,N} = \sum_{\sigma} \prod_{1 \leq l \leq r} e^{-\beta H_N(\sigma, l)}$$

we define

$$Z_{r-1,N}^{\zeta_{r-1}} = \mathbb{E}_{l-1} Z_{l,N}^{\zeta_{l-1}}$$

for any $0 \leq l \leq r - 1$.

We mention that for $r = 1$ and a generic $\zeta_0 > 0$ the model was studied and solved by Talagrand in [22]. If $\zeta_0 \to 0$ we recover the SK model at inverse temperature $\beta$. 

3.
The recursive definition (10) of the pressure per particle entails an equilibrium measure characterized by a hierarchical sequence of averages. As example, by (12) and using gaussian integration by parts, the internal energy of the system can be represented as follow

\[
\frac{\partial p_N}{\partial \beta} = \frac{\beta^2}{2} \left( 1 - \sum_{l=1}^{r} (\zeta_l - \zeta_{l-1}) \gamma_l^2 \langle q_{12}^2 \rangle_l \right)
\]  

(13)

where \( q_{12} \) is the overlap (9) and \( \langle \rangle_l \) is a suitable average (see [3, 11] for a precise definition) representing the partial thermalization at the level \( l \).

The multi-bath equilibrium can be described as follows: we start supposing that the spin variables thermalize at inverse temperature \( \beta \) and then, for any \( l = 1, \ldots, r \), we thermalize the random couplings \( J^0 \) with an inverse temperature \( \beta/\zeta_l - 1 \) and an effective Hamiltonian \( \log Z_l \), and so on.

2.1. The order parameter and the variational problem

It turns out [3] that the order parameter of the model is a distribution function on \([0, 1]\), however, comparing to the Sherrington–Kirkpatrick model, here it must satisfy an additional condition that preserves the multibath structure fixed at the beginning (see equation (13)). Consider an arbitrary integer \( k \geq r \) and a sequence \( \xi = (\zeta_j)_{j \leq k} \) such that

\[
0 = \xi_{-1} < \xi_0 < \xi_1 < \ldots < \xi_k = 1.
\]  

(14)

Moreover we assume that

\[
\zeta \subseteq \xi.
\]  

(15)

Now given the sequence \( \xi \) in (14) consider the following subset of \( \{0, \ldots, k\} \)

\[
K_l = \{ j : \xi_{l-1} < \xi_j \leq \zeta_l, 0 \leq j \leq k \}
\]  

(16)

for any \( l \leq r \). Given the sequence \( \gamma \) in (6) we construct a new sequence \( \tilde{\gamma} = (\tilde{\gamma}_j)_{j \leq k} \) defining for any \( j \leq k \)

\[
\tilde{\gamma}_j = \gamma_j \text{ if } j \in K_l.
\]  

(17)

We also introduce an arbitrary sequence \( q = (q_j)_{j \leq k} \) such that

\[
0 = q_0 \leq q_1 \leq \ldots \leq q_k = 1
\]  

(18)

and we define a sequence

\[
c = (\tilde{\gamma}_j q_j)_{j \leq k}.
\]  

(19)

Given the sequences \( \xi \) and \( c \) the order parameter of the model is the piecewise constant function \( x : [0, 1] \to [0, 1] \) defined as

\[
x(c) = \xi_j, \ c \in [c_{j-1}, c_j)
\]  

(20)

for any \( j = 1, \ldots, k \) and \( x(1) = 1 \).

Then the order parameter \( x(c) \in X_\xi \), where \( X_\xi \) is the space of distribution functions on \([0,1]\) that contains \( \zeta \) in the image. Physically \( x(c) \) represents the distribution of the overlap w.r.t. the multi-bath equilibrium measure previously introduced. Notice that conditioning on the event \( K_l \) you get
\[ \mathbb{E}(c^2) = \sum_{l=1}^{r} \mathbb{E}(K_l) \gamma_l^2 \mathbb{E}(q^2|K_l) \]

\[ = \sum_{l=1}^{r} (\zeta_l - \zeta_{l-1}) \gamma_l^2 \mathbb{E}(q^2|K_l) \]

which corresponds to the finite-volume decomposition in (13).

For example in the case \( r = 2 \) the model is determined by the parameters \( \zeta_0, \zeta_1 \) and \( \gamma_1 \) and a possible choice for \( x(c) \) with \( k = 6 \) is showed figure 1. In this case we have that the sets defined in (16) are

\[ K_2 = \{6, 5, 4\}, \quad K_1 = \{3, 2, 1\}, \quad K_0 = \{0\} \]

and then (17) leads to

\[ \tilde{\gamma}_{6,5,4} = 1, \quad \tilde{\gamma}_{3,2,1} = \gamma_1, \quad \tilde{\gamma}_0 = \gamma_0. \]

We want to emphasize that two important properties of \( x \) that holds for any choice of \( r, \zeta \) and \( \gamma \)

- condition (17) implies that \( \lim_{c \to 0^+} x(c) = \zeta_0 \), namely there is always a jump discontinuity in 0 with gap \( \zeta_0 \).
- any possible order parameter \( x \) has at least \( r \) levels of replica symmetry breaking.

In the next section we will give a physical interpretation of the above properties in the dynamical framework of the multibath equilibrium [4, 5].

Finally the solution of the model is given in terms of the following variational problem.

Let \( f(c, y; x) \) be a function of the variables \( c \in [0, 1], \ y \in \mathbb{R}, \) depending also on the order parameter \( x \) as the solution of the Parisi PDE

\[ \frac{\partial f}{\partial c} + \frac{1}{2} \left( \frac{\partial^2 f}{\partial y^2} + x(c) \left( \frac{\partial f}{\partial y} \right)^2 \right) = 0 \]

with final condition

\[ f(1, y) = \ln \cosh(\beta y). \]

We define the Parisi functional for the multiscale SK model the quantity

\[ \mathcal{P}(x) = \log 2 + f(0, h; x) - \frac{\beta^2}{2} \int_0^1 x(c) c \, dc. \]

Then it is possible to prove [3] that the thermodynamic limit of the quenched pressure density of the multiscale SK model \( p_N \) exists and is given by

\[ \lim_{N \to \infty} p_N = \inf_{x \in \mathcal{X}_c} \mathcal{P}(x). \]

2.2. Sketch of the proof

The strategy is to start with the following representation of the recursive definition (12). Let us denote by \( \alpha \in \mathbb{N}^r \) an auxiliary degree of freedom of the system. A configuration is now is

\[ (\sigma, \alpha) \in \Sigma_N \times \mathbb{N}^r \equiv \Sigma_N,\alpha. \]
Let $\nu_\alpha \in N_r$ be the random weights of RPC associated to the sequence $\zeta$ (see [3]). For $\alpha, \beta \in N_r$ we denote

$$\alpha \wedge \beta = \min \{0 \leq l \leq r \mid \alpha_1 = \beta_1, \ldots, \alpha_l = \beta_l, \alpha_{l+1} \neq \beta_{l+1}\}$$

(29)

Then $\alpha \wedge \beta$ denotes the level of their common ancestor.

Consider a gaussian process $H_N$ on $\Sigma_{N_r}$ defined by

$$H_N(\sigma, \alpha) = \frac{1}{\sqrt{N}} \sum_{i,j=1}^{N} g_{ij}(\alpha) \sigma_i \sigma_j$$

(31)

where $(g_{ij}(\alpha))_{i,j=1,...,N}$ is a family of i.i.d. copies of $g(\alpha)$.

Given two configurations $(\sigma^1, \alpha^1), (\sigma^2, \alpha^2) \in \Sigma_{N_r}$, the covariance of the process $H_N$ is

$$\mathbb{E} H_N(\sigma^1, \alpha^1) H_N(\sigma^2, \alpha^2) = N (c_{12})^2$$

(32)

where

$$c_{12} = \gamma_{\alpha^1 \wedge \alpha^2} q_N(\sigma^1, \sigma^2).$$

(33)

Notice that $q_N(\sigma^1, \sigma^2)$ is the usual overlap between two configurations $\sigma^1, \sigma^2 \in \Sigma_N$ while $\gamma_{\alpha^1 \wedge \alpha^2}$ is the overlap between two points in the space $N_r$ equipped with the random measure $(\nu_\alpha)_{\alpha \in N_r}$.

Then the pressure density of the multiscale SK model defined in (10) can be represented as

$$p_N(\beta) = \frac{1}{N} \mathbb{E} \log Z_N(\beta)$$

(34)
where
\[ Z_N(\beta) = \sum_{(\sigma, \alpha) \in \Sigma_N} \nu_{\alpha} e^{H_N(\sigma, \alpha)}. \]  
(35)

Within this formalism the proof of the main theorem is obtained by means of the upper bound obtained by a suitable interpolation and a lower bound by the cavity method. The main issue is to understand the distribution of \( c_{12} \) under the limiting Gibbs measure. The key point is that we have to know the joint probability distribution of the two covariances \( q_N \) and \( \gamma \). This situation is very similar to the case of the Multispecies SK model [1, 19] where it turns out that the Hamiltonian can be suitably perturbed in order to satisfy a synchronization property that allows to generate the joint probability of different overlap functions using the same RPC (see also [12, 17, 18] for recent applications of the synchronization method).

3. Dynamics

In [5] a dynamical approach, in the Langevin, as well in the Monte Carlo setting, was proposed to study the multi-bath equilibrium for a spin system. We notice that it is possible to modify the algorithm proposed there in order to get the equilibrium measure of the model considered here. Let us start for simplicity with the case \( r = 1 \) where the parameters of the model are \( \zeta_0 \) and \( \gamma_1 \), the general case \( r > 1 \) can be obtained through a similar construction. The recursive definition (12) implies that the equilibrium measure can be written as
\[ \mu_N(\sigma, J) = \mu_N(J) \mu_N(\sigma | J) \]  
(36)
where
\[ \mu_N(\sigma | J) = \frac{e^{-\beta H_N(\sigma)}}{Z_N} \]  
(37)
and
\[ \mu_N(J) = \frac{(Z_N)^{\zeta_0}}{E(Z_N)^{\gamma_0}}. \]  
(38)

The algorithm given in [5] is modified as follows. Consider a system of \( N \) spins \( \sigma = (\sigma_i)_{i \leq N} \) with energy
\[ H(\sigma, J) = \Gamma \sum_i J_{ij}\sigma_i\sigma_j + \frac{k}{2} \sum_{ij} J_{ij}^2 \]  
(39)
where \( \Gamma, k > 0 \) are two real parameters and \( J = (J_{ij})_{i,j \leq N} \) is a set of couplings. The dynamics goes as follows :

- the \( \sigma_i \) evolve with any dynamics (Glauber, Monte Carlo) associated with energy (39) and temperature \( T = \frac{1}{\beta} \).
- the \( J_{ij} \) (for \( i \leq j \) and \( J_{ij} = J_{ji} \)) evolve according to the Langevin equation:
\[ \gamma \dot{J}_{ij} = -kJ_{ij} - \Gamma \sigma_i \sigma_j + \rho_{ij}(t). \]  
(40)
The \( \rho_{ij} \) are uncorrelated white noises with zero mean and variance \( 2T^* \) where \( T^* = 1/\beta^* \) represents the temperature of the second equilibrium bath.
Given the spin configuration \( \sigma(t) \) then (40) implies that
\[
J_{ij}(t) = \int \, dt' \, e^{-\beta(t-t')}(-\Gamma \sigma_i(t')\sigma_j(t') + \rho_{ij}(t')).
\] (41)

Let us now define the timescale of the slow bath \( \tau_o = \frac{2}{\gamma} \), and assume that the equilibration time of the dynamics of the spins \( \sigma \) at given \( J \) is bounded by \( \tau_{eq} \). Clearly, \( \tau_{eq} \) may depend on the size of the system, and become infinite as \( N \to \infty \).

Considering now the case of timescale separation \( \tau_o \gg \tau_{eq} \) we may replace in (41) the product \( \sigma_i(t')\sigma_j(t') \) with its average \( \langle \sigma_i\sigma_j \rangle_J \) with respect to the stationary measure
\[
\mu(\sigma|J) = \frac{e^{-\beta(\sum \sigma_i J_{ij} \sigma_j)}}{Z(\beta, J)}. \] (42)

Since
\[
\langle \sigma_i\sigma_j \rangle_J = -\frac{1}{\Gamma \beta} \frac{\partial}{\partial J_{ij}} \log Z(\beta, J), \] (43)
the (40) becomes:
\[
\gamma \dot{J}_{ij} = -k J_{ij} + \frac{1}{\beta} \frac{\partial}{\partial J_{ij}} \log Z(\beta, J) + \rho_{ij}(t) \] (44)

and provides the following stationary measure for the \( J \):
\[
\mu(J) = \frac{e^{-\beta(\frac{1}{2} \sum \rho_{ij}^2 - \frac{1}{2} \ln Z(\beta, J))}}{\tilde{Z}(\beta, \beta^*)} \] (45)

where \( \tilde{Z}(\beta, \beta^*) \) is the normalization factor. It is easy to check that (45) matches (38) by setting \( \beta^*/\beta = \zeta_0 \) and \( \beta^* k = 1/(\gamma_1)^2 \).

A first remark is that if \( T^* = T \) the system is in contact with an equilibrium bath of temperature \( T \), whatever the timescales involved, or equivalently \( \beta^*/\beta = \zeta_0 = 1 \) corresponds to the annealed regime where the variables \( \sigma \) and \( J \) thermalize together. Instead if \( T^* \) goes to infinity then \( \zeta_0 \) goes to zero and the equilibrium is described by the usual quenched measure.

### 3.1. Stationarization

What we have argued above is that if the times \( \tau_o \) are sufficiently long, and the system size \( N \) is finite, the dynamic process above yields all the expectation values associated with the generating functional \( \frac{1}{\Gamma} \log E(Z^\phi) \). Let us discuss here, at a more phenomenological level, what we expect to happen in the case that the \( N \to \infty \) limit is taken first. When the \( J_{ij} \) are kept fixed, the dynamics never becomes stationary (two time correlations \( C(t, t_0) \) never become a function of \( (t - t_0) \); the system ages \([6] \). In order to understand what happens when the \( J_{ij} \) continuously change, we need to recall the physical intuition we have of the SK model landscape. What we know about this landscape is that if we change the \( J_{ij} \) by small amount
\[
\frac{\sum \rho_{ij}^2}{\sqrt{\sum \rho_{ij}^2 \sum \rho_{ij}^2}} = \epsilon
\]
where \( \epsilon \) is a small number of \( O(1) \), the structure of the lowest energy states is completely reshuffled. This strongly suggests, and indeed there is numerical evidence for this, that if the \( J_{ij} \) are continuously changing at a certain rate, the dynamics enters a regime in which it becomes stationary \( C(t, t') = C(t - t') \) (and yet, nonequilibrium), \( E(t) = \text{const} \), and follows the evolution at that rate. For the SK model one also believes, again based on the dynamic
solution [6], that when $\tau_0$ goes to infinity even after $N \to \infty$, the stationary value of the energy density is the same as the one with the limits reversed ($N \to \infty$ after $\tau_0 \to \infty$). This commutation of limits need not hold for other models such as the $p$-spin mean field model for $p > 2$, but, importantly, is expected to happen for finite-dimensional spin glasses with short-range interactions, the Edwards–Anderson model, for example. The argument in the latter case is simple, and may be seen as a simple generalization of the one given in [9] (more about this below): physical arguments indicate that metastable states of high free energy are unstable with respect to nucleation of a lower free-energy phase, the more unstable the higher they are. In a situation with slowly evolving couplings, there is a competition between the nucleation time $\tau_{\text{nucleation}}$ (a decreasing function of the free energy difference with the ground state), and the rate at which couplings change $\tau_0$. One expects then, roughly speaking, that all states with $\tau_{\text{nucleation}}$ will be constantly relaxed, and that one is left for $\tau_0 \to \infty$ with states close in free energy to the equilibrium one.

### 3.2. A phenomenological heat-exchange understanding

We make now an even more severely phenomenological discussion, which we believe however is illuminating. The out of equilibrium dynamics of the Sherrington–Kirkpatrick model has been solved (to the level of rigour of physics) in the out of equilibrium regime [6]. The two main actors of this solution are the two-point correlation function $C(t, t')$ and the integrated response $\chi(t, t')$ to a magnetic field that has been acting during an interval $[t', t]$, i.e. the magnetization at time $t$ per unit field acting on this interval. A result of the theory is that for large times, the parametric plot $\chi(t, t')$ versus $C(t, t')$ tends to a function $\chi(C)$ that for the Sherrington Kirkpatrick model happens to be directly related to the Parisi function $x(q)$ through

$$\frac{d\chi}{dC}|_{C=q} = x(q). \quad (46)$$

Franz et al [9] have argued that this coincidence between Parisi and dynamical relations must hold true for all finite-dimensional systems. Note that this is very surprising, because the dynamical results are obtained in the $t, t' \to \infty$ limit taken after $N \to \infty$, while equilibrium results concern the opposite limit. Although these developments are for the aging systems, the same can be done in the presence of multiple baths and the inversion of limits $\tau_0 \to \infty$ and $N \to \infty$. Another development of dynamics is the fact (see [7]) that the function $x(q)$ has the interpretation of an effective temperature that depends on the scale $q$, given by $T_{\text{eff}}(q) = \frac{T}{x(q)}$.

We are now in a position to interpret one of the main consequences of the solution of the model at the equilibrium presented in the previous section. Let us recall that any trial parameter $x$ must satisfies the condition $\lim_{c \to 0^+} x(c) = \zeta_0$, namely the Parisi solution starts at $x_{\text{min}} = \zeta_0$. It means that all effective temperatures $T_{\text{eff}}(q) = \frac{T}{x(q)}$ are smaller or equal than the effective temperature of the multibath $T^* = 1/\beta^* = 1/\beta_{G0}$. But this is just saying that the couplings $J_{ij}$ need to be hotter than the internal effective temperatures of the system, something automatically guaranteed by the quenched case where $\beta^* = 0$. This in turn means that the system does not give heat to the $J_{ij}$.

### 3.3. Perspectives for simulations and bound in finite-dimensional systems

We want to emphasize that if the arguments of stationarization and of commutation of the $N \to \infty$ and $\tau_0 \to \infty$ limits hold, one is then in a position to simulate a finite-dimensional Edwards–Anderson model for any given $\zeta_0$, and check whether there is a transition line in the
$T - \zeta_0$ plane, a necessary condition for arguing in favour of a Parisi RSB solution. One may would also be able to check the nature of the transition, which in turn might give an indication on the nature of the low-temperature phase. Studying a glass problem around its transition is of course much more efficient that deep in the glass phase, as witnessed by the work done over the years for the de Almeida–Thouless line.
