Abstract We analyse multiwavelength observations of an M2.9/1N flare that occurred in AR NOAA 11112 on 16 October 2010. AIA 211 Å EUV images reveal the presence of a faster coronal wave (decelerating from $\approx1390$ to $\approx830$ km s$^{-1}$) propagating ahead of a slower wave (decelerating from $\approx416$ to $\approx166$ km s$^{-1}$) towards the western limb. The dynamic radio spectrum from Sagamore Hill radio telescope shows the presence of metric type II radio burst, which reveals the presence of a coronal shock wave (speed $\approx800$ km s$^{-1}$). The speed of the faster coronal wave derived from AIA 211 Å images is found to be comparable to the coronal shock speed. AIA 171 Å high-cadence observations showed that a coronal loop, which was located at the distance of $\approx0.32R_\odot$ to the west of the flaring region, started to oscillate by the end of the impulsive phase of the flare. The results indicate that the faster coronal wave may be the first driver of the transversal oscillations of coronal loop. As the slower wave passed through the coronal loop, the oscillations became even stronger. There was a plasmoid eruption observed in EUV and a white-light CME was recorded, having velocity of $\approx340-350$ km s$^{-1}$. STEREO 195 Å images show an EIT wave, propagating in the same direction of the lower-speed coronal wave observed in AIA, but decelerating from $\approx320$ to $\approx254$ km s$^{-1}$. These observations reveal the co-existence of both waves (\textit{i.e.} coronal Moreton and EIT waves), and type II radio burst seems to be associated with the coronal Moreton wave.

Keywords: Solar flare – coronal loops, magnetic field, flux rope, magnetic reconnection.

1. Introduction

Large-scale coronal waves are often observed during solar eruptions. For example, the so-called EIT waves are the transient wavelike disturbances in the solar corona that propagate with the typical speed of 170–350 km s$^{-1}$ followed by the expanding coronal dimming (Thompson et al., 1998, Thompson et al., 1999, Klassen et al., 2000). These were first observed by EUV imaging Telescope (EIT) onboard SOHO (Delaboudinière et al., 1995). It is now widely accepted that EIT waves are associated with coronal mass ejections (CMEs) rather than solar flares (Delannée and Aulanier, 1999, Biesecker et al., 2002, Cliver et al., 2005, Chen, 2006). Regarding the spatial relationship between EIT waves and CMEs, some authors found that they are cospatial (Chen, 2009, Dai et al., 2010), whereas some others claimed that EIT wave fronts are ahead of the CME leading edge (Veronig, Temmer, and Vršnak, 2008, Patsourakos et al., 2009, Patsourakos and Vourlidas, 2009, Kienreich, Temmer, and Veronig, 2009, Kienreich et al., 2011, Veronig et al., 2010, Muhr et al., 2011). EIT waves were usually explained as the fast-mode magnetoacoustic waves in the corona (e.g., Wang, 2000, Wu et al., 2001), therefore they would be the coronal counterparts of the Hα Moreton waves that are observed in the chromosphere with a velocity of ≈500-2000 km s$^{-1}$ (Moreton and Ramsey, 1960). The fast-mode wave model was first questioned by Delannée and Aulanier (1999). Furthermore, Eto et al. (2002) investigated CME-related waves in an X-class flare event and found that EIT wave front is not cospatial with the Moreton wave front inferred from filament winking, and the propagation speeds of both waves were clearly different. Therefore, several non-wave models were later developed see (Wills-Davey and Attrill, 2009, Warmuth, 2010, Gallagher and Long, 2011, Chen, 2011, Zhukov, 2011) for reviews). On the basis of MHD numerical simulation, Chen et al. (2002) proposed that EIT waves are apparently moving brightenings, which are generated by the successive stretching of the closed field lines pushed by an erupting flux rope. According to the field-line stretching model (Chen et al., 2002, Chen, Fang, and Shibata, 2005), a fast-mode magnetoacoustic wave (or coronal Moreton wave) should be ahead of the EIT wave in a CME event, which was confirmed by Harra and Sterling (2003). Recently, using the high-resolution SDO/AIA observations, Chen and Wu (2011) convincingly reported the existence of the fast-mode coronal Moreton wave (i.e. coronal counterpart of Moreton wave), which is three times faster than the EIT wave.

Whereas EIT waves show a good correlation with the decimetric type II radio bursts, the speed derived from the type II radio burst is usually three times larger than the EIT wave speed (Klassen et al., 2000). The speed of Moreton wave, however, matches with the speed derived from type II radio bursts (Eto et al., 2002, Warmuth et al., 2004b). This suggests that the Moreton wave, rather than the EIT wave, and the type-II radio burst are two aspects of a single phenomenon, or the MHD fast-mode shock propagating in the corona.
Large-scale Coronal Waves and Loop Oscillations

(Uchida, 1974). Furthermore, note that there is a significant fraction of events where EIT waves are found to be a coronal signature directly associated with Moreton waves, i.e., both are cospatial (Warmuth et al., 2001; Warmuth et al., 2004b; Warmuth, Mann, and Aurass, 2005; Vršnak et al., 2002; Veronig et al., 2006; Muhr et al., 2010).

Besides the debates on EIT waves, the origin of coronal shock waves (usually evident in the form of type II radio burst) is also under debate (for detail please see, Warmuth, 2007; Chen and Fang, 2011). It may be driven by two possible physical mechanisms, i.e., (i) a blast wave ignited by the pressure pulse of a flare (Vršnak et al., 1995; Vršnak and Lulić, 2000a; Vršnak and Lulić, 2000b; Khan and Aurass, 2002; Narukage et al., 2002; Hudson et al., 2003; Magdalenić et al., 2010), (ii) a piston-driven shock due to a CME (Klassen et al., 1999; Klassen, Pohjolainen, and Klein, 2003; Cho et al., 2011). Thus, coronal shock waves may be associated with solar flares, CMEs, or some combination of these phenomena (Magara et al., 2000; Magdalenić et al., 2008; Vršnak and Cliver, 2008).

In this paper, we analyse the multiwavelength observations from SDO/AIA and STEREO to investigate the a large-scale coronal wave event and its impact on the solar corona in terms of loop oscillations. In Section 2, we will present multiwavelength observations of the large-scale coronal waves and the CME. In the last section, we will discuss the results and draw conclusions.

2. Observations

The Atmospheric Imaging Assembly (AIA: Lemen et al., 2012) on board the Solar Dynamics Observatory (SDO: Pesnell, Thompson, and Chamberlin, 2012) mission provides multiple high-resolution full-disk images of the corona and transition region. The field of view of each image is 1.3$R_\odot$. The pixel resolution of the images is 0.6$''$ and the cadence is 12 s. We use AIA 171, 211 and 193 Å EUV observations to investigate the evolution of coronal waves associated with an M2.9 flare that occurred in AR NOAA 11112 on 16 October 2010. The detailed description of flare energy build up and triggering mechanism has been discussed in Kumar et al. (2012) (hereafter Paper I). This paper consists of the description of flare/CME associated coronal waves kinematics as well as the interaction of these waves with the coronal loop, which showed transverse oscillations during the passage of the waves through it.

2.1. Coronal Waves

Figure [1] displays SDO/AIA 171 Å EUV image overlaid by SDO/HMI magnetogram contours to show the magnetic environment in a larger field of view. Red/blue represents positive/negative polarity field region. We can see a huge filament lying along the polarity inversion line (PIL), which did not erupt during the flare. The flare site is indicated by an arrow. A small loop system, indicated by another arrow, was located ≈0.32$R_\odot$ away from the flare site on its west side. Aschwanden and Schrijver (2011) have studied extensively the properties of the transversal oscillations of this loop system. They have interpreted it as a kink
Figure 1. SDO/AIA 171 Å image overlaid by HMI magnetogram contours (red=positive, blue=negative) showing a huge filament system lying along the polarity inversion line, and the sites of the flare and the oscillating loop system. The loop apex is marked by the ‘+’ symbol.

mode transversal oscillations and studied the properties of the MHD modes and diagnosed the local plasma conditions of the oscillating loop system. In particular, they noticed that, unlike most previously studied events, the oscillation of this coronal loop showed no damping for several periods.

In this paper, we only investigate the most probable driver of loop oscillations under the baseline of multiwavelength observations of the M-class flare and the associated large-scale wave phenomena. We use base-difference images to reduce the artifacts and for the correct information about the waves (Attrill, 2010). For investigating the driver of loop oscillations, we make AIA 211 Å base-difference images. The selected base-difference images are displayed in Figure 2. AIA 211 Å EUV images are sensitive to the temperature of 2 MK. The ‘+’ symbol marks the location of the small coronal loop in each image. The first image at 19:10:48 UT shows the flare site as well as the extended bright flare ribbon towards the west direction. We can see the propagating disturbance/wave towards west along the direction of bright ribbons (19:11:36 UT). Coronal dimmings were observed behind the propagating wavefront probably due to the depletion in plasma density. At 19:14:00 UT, the nearly circular shape of the fast wavefront is evident in the image, which is indicated by the arrows and marked by ‘F’. At this time it approached the site of coronal loop system indicated by the ‘+’ symbol (shown in 171 Å image, Figure 1), which started to oscillate. The ‘F’ front continued to expand towards west in a ballooning shape and it could be tracked close to the western limb (shown by arrows at 19:16:24 UT). In the meanwhile, we see another bright wavefront at 19:16:24 UT behind the faster front, which was also approaching the loop site. This is a slow wavefront, indicated by ‘S’
Figure 2. SDO/AIA EUV 211 Å base-difference images showing the propagation of coronal waves (indicated by arrows). The location of the oscillating coronal loop apex is indicated by the ‘+’ symbol in each image. The loop started oscillating when the leading edge of the faster wave approached the loop system. White line ‘A’ shows the great circle along the solar surface in the direction of wave propagation. The faster and slower waves are indicated by ‘F’ and ‘S’, respectively.
Figure 3. SDO/AIA EUV 193 Å base-difference images showing the propagation of coronal waves (indicated by the arrows). The location of the oscillating coronal loop apex is indicated by the ‘+’ symbol in each image. The line indicated by ‘B’ shows the slice cut along the direction of wave propagation. The faster and slower waves are indicated by ‘F’ and ‘S’, respectively.

(19:20:12 UT) and it slowly passed through the loop site (see images at 19:20:12 and 19:24:48 UT). Therefore, these images reveal the existence of both faster and slower coronal waves which propagated towards the west side of the flare site.

Figure 3 displays the selected base-difference images during the flare. We plot a larger field of view in these images in order to show the propagation of the faster wave from the solar disk to above the limb. The dome-like expansion of the faster wavefront (‘F’) can be seen in these images like AIA 211 Å. The faster (‘F’) and slower (‘S’) wavefronts can be seen simultaneously in the image at 19:20:07 UT. To show the propagation of the faster wavefront, we select a slice cut (indicated by ‘B’) in the plane of the sky along the wave propagation direction close to the western limb. The space-time plots of these two slices (A and B) are shown in Figure 4. The top panel shows the space-time plot of AIA 211 Å intensity distributions along slice ‘A’ (refer to image 19:15:12 UT in Figure 2). The top panel shows the propagating bright fast and slow wavefronts ‘F’ and ‘S’. The coronal dimming behind these fronts is evident in these plots. We measured the distance-time of these two propagating wavefronts using the top panel. The measured data points are indicated in the top panel by red (diamond) and blue (+) for faster and slower wave components. We apply the linear fit to these data points and attain the speeds of these waves, which are 1086 km s\(^{-1}\) and 276
Figure 4. Time evolutions of the 211 Å and 193 Å base-difference intensity distributions along slice ‘A’ (top) and slice ‘B’ (bottom), respectively. Faster and slower waves are marked by ‘F’ and ‘S’, respectively. The mean speeds (from the linear fit) of the faster and slower waves are respectively \( \approx 1086 \text{ km s}^{-1} \) and \( \approx 276 \text{ km s}^{-1} \).

However, we did not observe any filament or flux rope eruption in AIA EUV images during the flare event. A small loop eruption was observed from the flare site visible in high cadence AIA 94 Å images (Paper I), which moved along the westward direction. The top panel of Figure 5 displays the selected AIA 193 Å running-difference images above the solar western limb across which the wave propagates. The first image at 19:20:07 UT shows the bright circular fast wavefront (indicated by arrows), marked by ‘F’. In the next images, we can roughly see the shock front straddling over the leading edge of the expanding CME loop. For investigating the CME that was associated with the M2.9 flare,
Figure 5. Top panel: AIA 193 Å base-difference images showing the propagating faster wave-front ‘F’ ahead of expanding CME loop. The size of each image is 380”的×700”。 Bottom panel: AIA 193 Å and LASCO C2 composite difference images showing the CME associated with the flare with a speed≈350 km s⁻¹.

we use LASCO C2 *(Large Angle Spectrometric Coronagraph)* white light observation between ≈2-6 R⊙ ([Brueckner et al., 1995]). The bottom panel of Figure 5 displays the white light running-difference images, which are combined with AIA 193 Å EUV running-difference images of the same time. These images show the CME propagation away from the western limb. The second image at 19:24:06 UT shows the expanding CME loop in the AIA field of view, and we see the bright blob-shaped CME structure. In the coronograph field of view, the CME speed measured from the linear fit is found to be 350 km s⁻¹, and it shows an acceleration of 47.5 m s⁻² during the propagation. The fast shock disappeared in the LASCO field of view and we could observe only a blob-shaped structure in the CME (refer to image at 20:36:05 UT). This blob may be linked with the narrow coronal loop, which erupted along with the flare observed in AIA 94 Å images.
We used the STEREO-A (Solar TERrestrial Relations Observatory, Kaiser et al., 2008) EUV 195 Å images to see the coronal waves from a different viewing angle. The size of each image is 2048×2048 pixels with a 1.6″ per pixel sampling (Wuelser et al., 2004). In STEREO-A, the active region was located close to the eastern limb. The top panel of Figure 6 shows the 195 Å EUV running-difference images, where we can see a typical EIT wave. We can compare the direction of the EIT wave, which is the same as the slower one seen in the AIA 211 Å base-difference images. In order to estimate the speed of the EIT wave, we have visually tracked the position of the propagating wavefront along the great circle shown in Figure 6.

The inner coronagraph (COR1) of the Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI, Howard et al., 2008) instrument on board STEREO allows us to investigate the CME kinematics in the low corona from 1.4-4.0 R☉ with a high time cadence ≈5 or 10 min and a spatial resolution of 3.75″. We used COR1 observations to view the CME during the flare. The bottom panel of Figure 6 displays the base-difference images of the associated
CME observed by COR1. These images confirm a weak and slow CME, which was possibly associated with small loop eruption observed in AIA 94 Å images. The estimated speed of the CME from COR1 height-time measurements was \( \approx 340 \text{ km s}^{-1} \), which is close to the CME speed measured by LASCO C2 (\( \approx 350 \text{ km s}^{-1} \)).

The top panel of Figure 7 displays the dynamic radio spectrum in 25-180 MHz observed at Sagamore Hill radio station, USA (Straka and Castelli, 1970). We can see the type III and metric type II radio burst during the flare time. The drifting stripes of metric type II emission (i.e. fundamental and second harmonic) are known as the signature of coronal shock waves and radio emission frequencies can be converted into emission heights of the shock by adopting a coronal density model. We used the middle of the emission lane for the fundamental (+) and second harmonic (*) bands. We estimated the shock heights by using one-fold Newkirk coronal density model (Newkirk, 1961). The corresponding emission heights for both bands have been plotted in bottom panel of Figure 7 which shows the emission heights in between 1.3-1.5 \( R_\odot \) (from the Sun center). Using the linear fit to the emission heights, we estimated the shock speed from fundamental and second harmonic, i.e. \( \approx 800 \text{ km s}^{-1} \) and 680 km s\(^{-1}\) respectively. We
Figure 8. Top panel: Distance-time profiles of the coronal waves derived from AIA 211 (circle and plus symbols) and STEREO 195 Å (triangle) images. GOES soft X-ray profile in 1-8 Å wavelength band is depicted as the red curve. Duration of the type II radio burst is marked by a blue horizontal line. Middle panel: Speed profiles for both faster and slower wave. The plasmoid speed (red diamond) and coronal shock speed derived from type II (star) radio burst have also been plotted. Bottom panel: Space-time plot of the oscillating loop along slice cut shown in the left-panel of Figure 10.
also use two-fold Newkirk coronal density model, to estimate the uncertainty caused by (provisional) choice of the density model. The radio-source heights estimated using this model are larger in comparison to previous one (shown by red color). The mean speed of the shock from fundamental and second harmonic are \( i.e. \approx 975 \text{ km s}^{-1} \) and \( 830 \text{ km s}^{-1} \) respectively. We also plotted the projected height of the plasmoid (diamond) measured from AIA 94 Å images and the mean speed of the plasmoid was found \( \approx 1197 \text{ km s}^{-1} \). The plasmoid was observed nearly 3 min prior to the type II radio burst, which may be associated with the formation of shock wave in the corona.

These measurements of the traveling distance of the waves, along with GOES soft X-ray (1-8 Å) flux, are plotted in the top panel of Figure 8. The ‘circle’ and ‘plus’ symbols correspond to the AIA 211 Å measurements whereas ‘triangle’ symbol corresponds to the STEREO 195 Å. We measured the position the wave fronts ‘F’ and ‘S’ at different times using the AIA 211 Å slice ‘A’ in Figure 4. The position of the leading edge of the EIT wave shown in STEREO 195 Å images has been measured by drawing a great circle from the flare center (indicated in the top panel of Figure 6.) The measured speeds of these waves are plotted in the middle panel. For AIA observations, the speed of the faster wave decreases from \( \approx 1390 \text{ to } \approx 830 \text{ km s}^{-1} \), whereas that of the slower wave decreases from \( \approx 416 \text{ to } \approx 166 \text{ km s}^{-1} \). In STEREO, the speed of the EIT wave decreased from 320 to 254 km s\(^{-1}\). The faster wave showed a significant deceleration within the first 5 min. The average deceleration of the faster wave is \( \approx -2830 \text{ m s}^{-2} \), whereas \( \approx -350 \text{ m s}^{-2} \) for slower wave. Note that the uncertainty in the speed estimation is mainly due to the error in the distance measurement in AIA and STEREO, which is taken as 4 pixels (i.e. 2.4′′ for AIA and 6.4′′ for STEREO).

The speed difference between the EIT wave in STEREO and the faster wave in AIA implies the existence of two coronal waves, one faster and another slower wave, which again confirms our result in Figure 4. The speed of the slower wave in AIA is comparable to that observed in STEREO. The faster wave was missed by STEREO. This is probably due to the low cadence of STEREO, which is not sufficient to detect the faster wave (Chen and Wu, 2011). Therefore, the EIT wave in STEREO is not cospatial with the fast coronal wave observed in AIA. The observational evidence of the coronal Moreton wave ahead of the EIT wave (using AIA data) was recently confirmed by Chen and Wu (2011). They found that the speed of the coronal Moreton wave was nearly three times higher than the EIT wave speed. The present observations also most likely reveal the existence of the fast-mode MHD coronal Moreton wave ahead of the EIT wave. In Figure 5, we also included the mean speed of the plasmoid (red diamond) and mean speed of the coronal shock (star) measured from the drift rate of type II (fundamental band), which show the good correspondence between all the speeds.

In order to investigate the magnetic field environment of the active region, we used the potential field source surface (PFSS) extrapolation (Altschuler and Newkirk, 1969; Schatten, Wilcox, and Ness, 1969) before the flare event at 18:04 UT. Figure 9 shows the PFSS extrapolation of the active region. The flare site, the coronal wave, and the oscillating loop are indicated by arrows. Comparing the PFSS extrapolation with AIA 211 Å images reveals that the field line above
the flare site seems to be stretched during the wave propagation. Note that the lateral expansion of the wave/dimming (the direction from the southwest to the northeast) is negligible. It is probably because the magnetic field lines along the narrow corridor are closed inside the corridor rather than linking outside, and only these field lines responded to the CME eruption.

2.2. Coronal Loop-Oscillation

The right panel of Figure 10 displays the AIA 211 Å EUV base-difference image at 19:14:00 UT in the enlarged view showing the wavefronts (indicated by arrows) of both fast and slow waves, which are marked respectively by ‘F’ and ‘S’. The position of the loop apex is marked by ‘+’ symbol. This gives a clear indication of the successive interaction of the faster and slower waves with the coronal loop. The AIA 171 Å image in the left panel shows the position of the loop that presented transverse oscillations (indicated by the red arrow, and the online 171 Å movie) during the passage of coronal waves. The location of the slice cut for the space-time plot is marked as the white line in this image, and the space-time plot is presented in the lower panel of Figure 8.

The loop started oscillating when the leading front of the faster wave approached it (see aia171.avi, the online movie for loop oscillations). The space-time plot reveals that the amplitude of the oscillation of selected thread shows an increase before a weak decay, which is very unusual for coronal loop oscillations (Aschwanden and Schrijver, 2011). The loop oscillation continued about five
Figure 10. Left: AIA 171 Å EUV image showing the loop, which presented transverse oscillations (indicated by the red arrow) during the passage of coronal waves. The position of the slice cut for space-time plot is marked as the white line in the image. Right: AIA 211 Å EUV base-difference image showing the wavefronts (indicated by arrows) of both the faster and the slower wave, marked by ‘F’ and ‘S’, respectively. The position of the loop apex is marked by the ‘+’ symbol.

periods and the measured period of oscillation was 6.3 minutes. These measurement of the oscillation period of the loop strand matches well with the findings of Aschwanden and Schrijver (2011). However here, our aim is to shed light on the most likely driver of the coronal loop oscillations. We mark the arrival times of the faster and slower waves to the coronal loop in the space-time plot, and it seems that the faster coronal wave is the first driver to generate the loop oscillations. In addition, type II radio burst was also observed at the time of coronal wave propagation towards west. The duration of type II is indicated by a horizontal line in the top panel of Figure 8. The arrival of propagating faster wave, its relation with the flare, the metric type II radio burst, and the starting of loop oscillation, collectively indicate that the coronal loop started to oscillate due to its interaction with a coronal shock wave.

The peculiar behavior of this loop oscillation event is that the oscillation did not show strong decay as usual, and instead, its amplitude was increasing in the first two periods. In this sense, it should be noted that the slower wave (EIT wave) passed through the location of coronal loop after the faster wave. The EIT wave arrived at the loop at about 19:16:24 UT (refer to Figure 8). Coincidentally, the amplitude of the oscillation increased after the arrival of the EIT wave (front S) and became stronger (bottom panel of Figure 8). The loop oscillation was observed till the wave passed there. Later when it moved out, loop oscillations decayed weakly. Therefore, it is likely that the passage of the slower wave caused the stronger loop oscillation for a longer time.

Eto et al. (2002) also have found that the filament winking was initiated by the passage of a Moreton wave, and was enhanced when the EIT wave passed the filament. In their study, the times of visibility for the Moreton wave did not overlap with those of the EIT wave. Instead, the continuation of the Moreton wave was implied by the filament oscillation. Using the position and speed measurements, they clearly showed that the Moreton wave differed physically from...
the EIT wave in their case. In our case, the loop oscillation behavior generated by the impact of the faster and the slower coronal waves are consistent with the filament oscillations initiated by the passage of the Moreton and EIT waves. Recently, Asai \textit{et al.} \citeyear{2012} have reported the first simultaneous observation of an Hα Moreton wave, the corresponding EUV fast coronal waves, and a slow and bright EIT wave. They also observed the filament/prominence oscillations when the wave approached it. However, we do not have the Hα observations during the flare. But, we see the propagating brightening/disturbance in AIA 304 Å images (correspond to chromosphere and transition region) in the similar direction of the EUV wave, visible in AIA 211 and 193 Å images. Our observational findings are also consistent with Asai \textit{et al.} \citeyear{2012}.

3. Discussion and Conclusions

We analyzed the multiwavelength observations of the M2.9/1N flare occurred on 16 October 2010 from AR NOAA 1112. We first discuss the identification of two waves associated with the flare/CME event, \textit{i.e.}, a faster coronal Moreton wave and a slower EIT wave. According to the SDO/AIA observations, the flare and the CME were associated with a faster and a slower waves, which moved towards the west decelerating from \(\approx 1390\) to \(\approx 830\) km s\(^{-1}\) and from \(\approx 416\) to \(\approx 166\) km s\(^{-1}\), respectively. In STEREO 195 Å only one diffuse EIT wave was discernable, decelerating from \(\approx 320\) to \(\approx 254\) km s\(^{-1}\). The slower wave in SDO/AIA is interpreted as a classical EIT wave, consistent with the STEREO observations.

According to Uchida’s Model \citeyear{1968, 1970}, the Moreton wave is a sweeping skirt on the chromosphere of the MHD fast-mode shock wave which propagates in the corona. Therefore, this model predicts the existence of a coronal counterpart of the chromospheric Moreton wave at the same place and with the same velocity as that of the Moreton wave. \cite{Thompson \textit{et al.} \citeyear{2000}} reported that there are two components in EIT waves, \textit{i.e.}, bright/sharp and diffuse EIT waves. The sharp EIT wave and Hα Moreton wave are cospatial, whereas the relationship between the diffuse EIT and Moreton wave was not clear. In the present event, we observed the diffuse EIT wave in STEREO 195 Å images, which was cospatial with the slower wave observed by SDO/AIA. \cite{Wu \textit{et al.} \citeyear{2001} and Warmuth \textit{et al.} \citeyear{2001}} suggested that the diffuse EIT waves are decelerated Moreton waves, namely that not only the sharp EIT waves but also the diffuse EIT waves are coronal counterparts of the chromospheric Moreton waves. However, \cite{Eto \textit{et al.} \citeyear{2002}} found that the diffuse EIT wave was not the coronal counterpart of the chromospheric Moreton wave in their analysed event. In the present paper, we revealed the existence of both faster and slower wavefronts, which are not co-spatial. In addition, they have very different velocities. The existence of these two waves is consistent as predicted in Chen \textit{et al.} \citeyear{2002} model and it was confirmed by \cite{Harra and Sterling \citeyear{2003} and Chen and Wu \citeyear{2011}}.

A remote small coronal loop started to oscillate with a period of 6.3 minutes as the faster wave hit it. The detailed study of the loop oscillation has been presented by Aschwanden and Schrijver \citeyear{2011}. We suggest that the faster
wave is most likely the first driver of loop oscillation, and the oscillation was enhanced by the ensuing EIT wave. PFSS extrapolation and the direction of the fast wavefront in association with loop oscillation suggest that the coronal Moreton wave propagates across the closed magnetic loops. The visibility of the coronal Moreton wave may be related to the local magnetic field, and tends to be enhanced at weaker magnetic field (Uchida, 1970).

The initiation of a filament oscillation that preceded the arrival of the EIT wave in Eto et al. (2002) was suggested as evidence in support of the idea that EIT waves are not coronal Moreton waves. On the other hand, Warmuth et al. (2004b) interpreted this event in terms of a tilted coronal wavefront: since the filament is located higher up, the more tenuous upper – and thus less observable – parts of the wavefront will reach it first. Furthermore, determining at which time the filament actually begins to oscillate can be quite ambiguous, so that the possible errors can be much larger than the errors on the wavefronts (Warmuth, 2010). But, in the present case, we have shown that the triggering of loop oscillation at the arrival of the faster wavefront, and that the oscillation was enhanced with the passage of the slower wavefront, i.e. the EIT wave.

A metric type II burst was also observed during the propagation of coronal waves. The speed of the shock wave derived from type II frequency drift rate (≈800 km s$^{-1}$) matches well with the speed of the faster coronal wave associated with the flare/CME. The type II radio burst may be associated with the high speed coronal wave as it moves nearly with Alfvénic speed in the corona. The observed faster coronal wave is probably the fast-mode coronal Moreton wave, and the presence of type II during this time supports the presence of a fast-mode MHD shock wave as predicted by Uchida (1974). We found good temporal, spatial and speed matching between EUV coronal Moreton wave and the shock wave derived from type II radio burst.

In a statistical analysis of coronal loop oscillations observed by TRACE, Hudson and Warmuth (2004) showed the strong association of TRACE loop oscillation events with type II bursts indicating that some of them were directly caused by blast waves. In their observations, only certain loops oscillate, whereas other nearby loops remain stationary, which was consistent with the highly directional nature of blast waves (Smith and Harvey, 1971). On the other hand, a piston-driven-type shock could be launched by ejecta with a smaller scale (e.g., sprays or ejecta observed with the Yokohoh soft X-ray telescope instead of an initial pressure pulse. For example, Klein et al. (1999) have shown X-ray blob (projected speed≈770 km s$^{-1}$) as a plausible driver of a fast shock in the corona. They could act as a temporary piston, and either they could generate a perturbation that then steepens into a shock or there could be a short phase of a driven shock, after which the shock propagates freely (Warmuth et al., 2004b). In the present case, we observe (in AIA 94 Å images) a high speed plasmoid (projected speed≈1197 km s$^{-1}$) moving away from the flare site during the flare impulsive phase (Paper I) and this eruption may be responsible to drive high speed shock and type II observed in this event. This favors the scenario for the piston driven shock.

Recently, Warmuth and Mann (2011) analysed large sample of 176 EIT wave events and based on their kinematical behavior, they found the evidence for
three distinct populations of coronal EUV waves: initially fast waves (v  \geq 320 \text{ km s}^{-1}) that show pronounced deceleration (class 1 events), waves with moderate (v \approx 170-320 \text{ km s}^{-1}) and nearly constant speeds (class 2), and slow waves (v \leq 130 \text{ km s}^{-1}) showing a rather erratic behavior (class 3). They explained class 1 and 2 in terms of the fast mode wave/shock model, whereas class 3 events due to the magnetic reconfiguration. By combining data from AIA and EIS, Harra et al. (2011) and Veronig et al. (2011) examined a coronal wave and found that the main wave front travels at \approx 500 \text{ km s}^{-1} and is strongly redshifted (i.e., as the wave propagates it also pushes plasma downward with a speed of \approx 20 \text{ km s}^{-1}). They concluded that the observed wave was generated by the outgoing CME, as in the scenario for the classic Moreton wave (i.e., fast MHD wave), which pushes down the chromospheric plasma along the shock front.

Our observations reveal the signature of fast coronal Moreton wave and associated loop oscillation that was initiated by its interaction. On the other hand, the slower wave observed in this event cannot be the top part of the CME leading loop since it impacted the small coronal loop. It could be associated with the leg of the CME leading loop, while EIT wave was already found to be cospatial with the CME leg (Chen, 2009; Dai et al., 2010). Therefore, we conclude that the slower wave is the classical EIT wave.

In conclusion, we presented the multiwavelength observations of both the faster and slower coronal waves, which may be the first and the second drivers of the oscillations of a remote loop. Using the high spatial and temporal data from space and ground based instruments, further studies should be performed in order to shed more light on the flare processes and their association with large-scale coronal waves.

Acknowledgements We express our gratitude to the referee for his/her valuable and constructive comments/suggestions which improved the manuscript considerably. SDO is a mission for NASA’s Living With a Star (LWS) Program. We thank the STEREO/SECCHI teams for their open data policy. We are thankful for the radio data obtained from Sagamore Hill station. SOHO is a project of international cooperation between ESA and NASA. PFC is supported by the Chinese foundation NSFC (11025314, 10878002, and 10933003) and 2011CB811402. PK thanks to Prof. D.E. Innes for several fruitful discussions during his visit to MPS. PK thanks to Dr. A.K. Srivastava for reading/discussing the manuscript. This work has been supported by the “Development of Korea Space Weather Center” project of KASI, and the KASI basic research fund.
