We show that in fully self-consistent treatments of the pion, namely, its static properties and elastic and transition form factors, the asymptotic limit of the product \( Q^2 G_{\gamma^*\gamma\pi}(Q^2) \), determined \( a \) priori by the interaction employed, is not exceeded at any finite value of spacelike momentum transfer. Furthermore, in such a treatment of a vector-vector contact-interaction one obtains a \( \gamma^*\gamma \rightarrow \pi^0 \) transition form factor that disagrees markedly with all available data. We explain that the contact interaction produces a pion distribution amplitude that is flat and nonvanishing at the endpoints. This amplitude characterizes a pointlike pion bound state. Such a state has the hardest possible form factors (i.e., form factors that become constant at large momentum transfers and hence are in striking disagreement with completed experiments). However, interactions with QCD-like behavior produce soft pions, a valence-quark distribution amplitude that vanishes as \( \sim (1-x)^2 \) for \( x \rightarrow 1 \), and results that agree with the bulk of existing data. Our analysis supports a view that the large-\( Q^2 \) data obtained by the BaBar Collaboration is not an accurate measure of the \( \gamma^*\gamma \rightarrow \pi^0 \) form factor.

I. INTRODUCTION

The process \( \gamma^*\gamma \rightarrow \pi^0 \) is fascinating because in order to explain the associated transition form factor within the standard model on the full domain of momentum transfer, one must combine, using a single internally consistent framework, an explanation of the essentially nonperturbative Abelian anomaly with the features of perturbative QCD. The case for attempting this has received a significant boost with the publication of data from the BaBar Collaboration [1] because, while they agree with earlier experiments on their common domain of squared-momentum transfer [2,3], the BaBar data are unexpectedly far above the prediction of perturbative QCD at larger values of \( Q^2 \).

Herein we contribute toward understanding the discrepancy by analyzing this process using the Dyson-Schwinger equations (DSEs) [4–9], which are known to have the capacity to connect nonperturbative and perturbative phenomena in QCD. In particular, the connection between dynamical chiral symmetry breaking (DCSB) and the Abelian [10–16] and non-Abelian [17] anomalies is understood, as is the manner through which the perturbative QCD results for the large-\( Q^2 \) behavior of the transition form factor can be obtained [18,19].

As part of this analysis, we will elucidate the sensitivity of the \( \gamma^*\gamma \rightarrow \pi^0 \) transition form factor \( G_{\gamma^*\gamma\pi}(Q^2) \) to the pointwise behavior of the interaction between quarks. We will use existing DSE calculations [20] of this and the kindred \( \gamma^*\gamma \rightarrow \pi^0 \) form factor to characterize the \( Q^2 \) dependence of \( G_{\gamma^*\gamma\pi}(Q^2) \) which is produced by a quark-quark interaction that is mediated by massless vector bosons. For comparison, we will compute the behavior obtained if quarks interact instead through a contact interaction. Such comparisons are important to achieving a goal of charting the long-range behavior of the strong interaction in the standard model [21].

II. BOUND STATE PION

A. Bethe-Salpeter and gap equations

Poincaré covariance entails that the Bethe-Salpeter amplitude for an isovector pseudoscalar bound state of a dressed quark and antiquark takes the form

\[
\Gamma_j^\tau(k; P) = \tau^\dagger \gamma_5 \left[ i E_\tau(k; P) + \gamma_\mu \cdot P F_\tau(k; P) + \gamma_\mu k_\mu P \gamma_5 H_\tau(k; P) \right],
\]

(1)

where \( k \) is the relative and \( P \) the total momentum of the constituents, and \( \{\tau^\dagger, j = 1, 2, 3\} \) are the Pauli matrices.\(^1\) This amplitude is determined from the homogeneous Bethe-Salpeter equation (BSE)

\[
\left[ \Gamma_j^\tau(q; P) \right]_{\mu a} = \int \frac{d^4q}{(2\pi)^4} \left[ \chi_j^\tau(q; P) \right]_{\nu b} K_{\mu a}^{\nu b}(q, k; P),
\]

(2)

\(^1\)We employ a Euclidean metric with \( \{\gamma_\mu, \gamma_5\} = 2\delta_{\mu 5}; \gamma_5 = \gamma_1 \gamma_2 \gamma_3; \) and \( a \cdot b = \sum_{\nu=1}^{3} a_\nu b_\nu \). A timelike four-vector \( Q \) has \( Q^2 < 0 \). Furthermore, we consider the isospin-symmetric limit.
where \( \chi^2(q; P) = S(q + P)\Gamma^2(q; P)S(q) \); \( r, s, t, \) and \( u \) represent color, flavor, and spinor indices; and \( K \) is the quark-antiquark scattering kernel. In Eq. (2), \( S \) is the dressed-quark propagator, viz., the solution of the gap equation

\[
S(p)^{-1} = i\gamma \cdot p + m + \int \frac{d^4q}{(2\pi)^4} g^2 D_{\mu\nu}(p - q) \frac{\lambda^a}{2} \gamma_\mu S(q) \frac{\lambda^a}{2} \Gamma_\nu(p, q),
\]

(3)

wherein \( m \) is the Lagrangian current-quark mass, \( D_{\mu\nu} \) is the gluon propagator, and \( \Gamma_\nu \) is the quark-gluon vertex.

**B. Momentum-independent vector-boson exchange**

Following Ref. [22] we define

\[
g^2 D_{\mu\nu}(p - q) = \delta_{\mu\nu} \frac{1}{m^2_G},
\]

(4)

where \( m_G \) is a gluon mass scale (such a scale is generated dynamically in QCD, with a value \( \sim 0.5 \text{ GeV} \) [23]) and proceed by embedding this interaction in a rainbow-ladder truncation of the DSEs. This means \( \Gamma_\nu(p, q) = \gamma_\nu \) in both Eq. (3) and the construction of \( K \) in Eq. (2). Rainbow-ladder is the leading order in a nonperturbative, symmetry-preserving truncation [24,25]. It is known and understood to be an accurate truncation for pseudoscalar mesons [26,27].

With this interaction the gap equation becomes

\[
S(p)^{-1} = i\gamma \cdot p + m + \int \frac{d^4q}{(2\pi)^4} \frac{1}{3 m_G^2} \gamma_\mu S(q) \gamma_\mu.
\]

(5)

The integral possesses a quadratic divergence, even in the chiral limit. If the divergence is regularized in a Poincaré covariant manner, then the solution is

\[
S(p)^{-1} = i\gamma \cdot p + M,
\]

(6)

where \( M \) is momentum independent and determined by

\[
M = m + \frac{M}{3\pi^2 m_G^2} \int_0^\infty ds s \frac{1}{s + M^2}.
\]

(7)

To proceed we must specify a regularization procedure. We write [28]

\[
\frac{1}{s + M^2} = \int_0^\infty d\tau e^{-\tau(s + M^2)} - \int_0^{\tau_+} d\tau e^{-\tau(s + M^2)}
\]

\[
= \frac{e^{-\tau(s + M^2)}\tau_+ - e^{-\tau(s + M^2)}\tau_-}{s + M^2},
\]

(8)

(9)

where \( \tau_{\text{ir}} \) are, respectively, infrared and ultraviolet regulators. It is apparent from Eq. (9) that a nonzero value of \( \tau_\text{ir} = 1/\Lambda_\text{ir} \) implements confinement by ensuring the absence of quark production thresholds [29,30]. Furthermore, since Eq. (4) does not define a renormalizable theory, \( \Lambda_\text{uv} := 1/\tau_\text{uv} \) cannot be removed but instead plays a dynamical role and sets the scale of all dimensionless quantities.

The gap equation can now be written

\[
M = m + \frac{M}{3\pi^2 m_G^2} C^u(M^2),
\]

(10)

where \( C^u(M^2)/M^2 = \Gamma(-1, M^2 r_+^2) - \Gamma(-1, M^2 r_-^2) \), with \( \Gamma(\alpha, \gamma) \) being the incomplete gamma function.

Using the interaction we specified, the homogeneous BSE for the pseudoscalar meson is \( (q_+ = q + P) \)

\[
\Gamma_\pi(P) = -\frac{4}{3} \frac{1}{m_G^2} \int d^4q \gamma_\mu \chi_\pi(q_+, q) \gamma_\mu.
\]

(11)

With a symmetry-preserving regularization of the interaction in Eq. (4), the Bethe-Salpeter amplitude cannot depend on relative momentum. Hence Eq. (1) reduces to

\[
\Gamma_\pi(P) = -\frac{1}{M} \gamma_S \left[ i E_\pi(P) + \frac{1}{M} \gamma \cdot PF_\pi(P) \right].
\]

(12)

Crucially, \( F_\pi(P) \), a component of pseudovector origin, remains. It is an essential component of the pion, which has very significant measurable consequences and thus cannot be neglected.

**C. Ward-Takahashi identity**

Preserving the vector and axial-vector Ward-Takahashi identities is essential when computing properties of the pion. The \( m = 0 \) axial-vector identity states

\[
P_\mu \Gamma_5(k_+, k) = S^{-1}(k_+)i\gamma_S + i\gamma_\mu S^{-1}(k),
\]

(13)

where \( \Gamma_5(k_+, k) \) is the axial-vector vertex, which is determined by

\[
\Gamma_5(k_+, k) = \gamma_\mu \gamma_\nu - \frac{4}{3} \frac{1}{m_G^2} \int d^4q \gamma_\mu \chi_5(q_+, q) \gamma_\nu.
\]

(14)

To achieve this, one must implement a regularization that maintains Eq. (13). To see what this entails, contract Eq. (14) with \( P_\mu \) and use Eq. (13) within the integrand. This yields the following two chiral limit identities:

\[
M = \frac{8}{3} \frac{M}{m_G^2} \int d^4q \left[ \frac{1}{q^2 + M^2} + \frac{1}{q_-^2 + M^2} \right],
\]

(15)

\[
0 = \int d^4q \left[ \frac{P_\mu q_+}{q_-^2 + M^2} - \frac{P_\mu q}{q_+^2 + M^2} \right],
\]

(16)

which must be satisfied after regularization. Analyzing the integrands using a Feynman parametrization, one arrives at the following identities for \( P^2 = 0 \):

\[
M = \frac{16}{3} \frac{M}{m_G^2} \int d^4q \frac{1}{(2\pi)^4 \left[ q_-^2 + M^2 \right]^2},
\]

(17)

\[
0 = \int d^4q \frac{1}{2} \frac{q^2 + M^2}{(2\pi)^4 \left[ q_-^2 + M^2 \right]^2}.
\]

(18)

Equation (17) is just the chiral-limit gap equation. Hence it requires nothing new of the regularization scheme. However, Eq. (18) states that the axial-vector Ward-Takahashi identity is satisfied if and only if the model is regularized so as to ensure there are no quadratic or logarithmic divergences. Unsurprisingly, these are just the circumstances under which a shift in integration variables is permitted, an operation required to prove Eq. (13).
We observe, in addition, that Eq. (13) is valid for arbitrary \( P \). In fact, its corollary, Eq. (15), can be used to demonstrate that in the chiral limit the two-flavor scalar-meson rainbow-ladder truncation of the contact-interaction DSEs produces a bound state with mass \( m_\pi = 2M \) [31]. The second corollary, Eq. (16), entails

\[
0 = \int_0^1 d\alpha \left[ \mathcal{C}^\text{in}(\omega(M^2, \alpha, P^2)) + \mathcal{C}_1^\text{in}(\omega(M^2, \alpha, P^2)) \right],
\]

with \( \omega(M^2, \alpha, P^2) = M^2 + \alpha(1-\alpha)P^2 \) and \( \mathcal{C}_1^\text{in}(z) = -z(d/dz)\mathcal{C}^\text{in}(z) \).

\[E_\pi(P), F_\pi(P) \]

\[
0 = \int_0^1 d\alpha \left[ \mathcal{C}^\text{in}(\omega(M^2, \alpha, P^2)) + \mathcal{C}_1^\text{in}(\omega(M^2, \alpha, P^2)) \right],
\]

\[
K_{\text{EE}} = \int_0^1 d\alpha \left[ \mathcal{C}^\text{in}(\omega(M^2, \alpha, -m^2_\pi)) + 2\alpha(1-\alpha)m^2_\pi\mathcal{C}_1^\text{in}(\omega(M^2, \alpha, -m^2_\pi)) \right],
\]

\[
K_{\text{EF}} = -m^2_\pi \int_0^1 d\alpha \mathcal{C}_1^\text{in}(\omega(M^2, \alpha, -m^2_\pi)),
\]

\[
K_{\text{FE}} = \frac{1}{2} M^2 \int_0^1 d\alpha \mathcal{C}_1^\text{in}(\omega(M^2, \alpha, -m^2_\pi))
\]

D. Pion's Bethe-Salpeter kernel

We are now in a position to write the explicit form of Eq. (11)

\[E_\pi(P), F_\pi(P) \]

\[
0 = \int_0^1 d\alpha \left[ \mathcal{C}^\text{in}(\omega(M^2, \alpha, P^2)) + \mathcal{C}_1^\text{in}(\omega(M^2, \alpha, P^2)) \right],
\]

with \( \mathcal{C}_1(z) = \mathcal{C}(z)/z \). We used Eq. (19) to arrive at this form of \( K_{\text{EF}} \).

In the computation of observables, one must use the canonically normalized Bethe-Salpeter amplitude; i.e., \( \Gamma_\pi \) is rescaled so that

\[P_\mu = N_\pi \text{tr} \int \frac{d^4q}{(2\pi)^4} \Gamma_\pi(-P) \frac{\partial}{\partial P_\mu} S(q + P) \Gamma_\pi(P) S(q).\]

In the chiral limit, this means

\[
1 = \frac{N_\pi}{4\pi^2 M^2} C_1(M^2; \tau^2_\pi, \tau^2_\pi) E_\pi [E_\pi - 2F_\pi].
\]

With the parameter values (in GeV) [22]

\[
m_G = 0.11, \quad \Lambda_\pi = 0.24, \quad \Lambda_{\pi\pi} = 0.823
\]

one obtains the results presented in Table I. We note that the leptonic decay constant and in-pion condensate are given by

\[f_\pi = \frac{1}{2\pi^2} \int \frac{d^4q}{(2\pi)^4} \langle 0 | \bar{q} q | q \rangle,\]

\[
f_\pi = \frac{3}{4\pi^2} \left[ E_\pi K_{\text{EF}}^{\pi^2 - m_\pi^2} + F_\pi K_{\text{FE}}^{\pi^2 - m_\pi^2} \right].
\]

In the chiral limit \( \kappa_\pi \rightarrow \kappa_\pi^0 = -\langle \bar{q} q \rangle \) (i.e., the so-called vacuum quark condensate [34]). Moreover, also in this limit, one may readily verify that [22]

\[
E_\pi = \frac{m_{\pi}}{f_\pi},
\]

which is a particular case of one of the Goldberger-Treiman relations proved in Ref. [32].

E. Dressed-photon-quark vertex

In coupling photons to a bound state constituted from dressed quarks, it is important that the quark-photon vertex be dressed so that it satisfy the vector Ward-Takahashi identity [12]. Indeed, where possible it should be dressed at a level consistent with the truncation used to compute the bound-state’s Bethe-Salpeter amplitude [35]. With our treatment of the interaction described in connection with Eq. (4), the bare vertex \( \gamma_\mu \) is sufficient to satisfy the Ward-Takahashi identity and ensure a unit value for the charged pion’s electromagnetic form factor at zero momentum transfer [22]. However, given the simplicity of the DSE kernels, one can readily do better.

A vertex dressed consistently with our rainbow-ladder pion is determined by the following inhomogeneous BSE:

\[
\Gamma_\mu(Q) = \gamma_\mu - \frac{4}{3 m_G^2} \int \frac{d^4q}{(2\pi)^4} \gamma_\alpha \chi_\mu(q + q) \gamma_\alpha,
\]

where \( \chi_\mu(q + q) = S(q + P) \Gamma_\alpha(Q) S(q) \). Owing to the momentum-independent nature of the interaction kernel, the general form of the solution is

\[
\Gamma_\mu(Q) = \gamma_\mu P_T(Q^2) + \gamma_\mu^L P_L(Q^2),
\]

where \( Q_\mu Y_\rho^T = 0 \) and \( Y_\mu^T + Y_\mu^L = \gamma_\mu \). This simplicity does not survive with a more sophisticated interaction.

Upon insertion of Eq. (32) into Eq. (31), one can readily obtain

\[P_T(Q^2) = 1,\]

owing to Eq. (16). Using this same identity, one finds

\[P_L(Q^2) = \frac{1}{1 + K_\gamma(Q^2)},\]

TABLE I. Results calculated with the parameter values in Eq. (27). \( m_\pi \) is obtained from Eq. (20); \( \kappa_\pi, f_\pi \) are defined in Eqs. (29) and (28); \( m_\mu \) is determined by solving Eq. (37); and the charge radii are discussed in connection with Eq. (38). The static properties are commensurate with the results from QCD-based DSE studies [33]. (Dimensioned quantities are listed in GeV or fm, as appropriate.)

| \( m_\pi \) | \( E_\pi \) | \( F_\pi \) | \( M \) | \( m_\pi \) | \( \sqrt{h_\pi} \) | \( f_\pi \) | \( m_\mu \) | \( r_q \) | \( r_\pi \) | \( r_\pi^0 \) |
|---|---|---|---|---|---|---|---|---|---|---|
| 0 | 4.28 | 0.69 | 0.40 | 0 | 0.22 | 0.094 | 0.90 | 0.34 | 0.30 | 0.45 |
| 0.008 | 4.36 | 0.72 | 0.41 | 0.14 | 0.22 | 0.094 | 0.91 | 0.33 | 0.30 | 0.44 |
with
\[
K_T(Q^2) = \frac{1}{3\pi^2 m_G^2} \int_0^1 d\alpha (1 - \alpha) Q^2 \tilde{C}_1^T(\omega(M^2, \alpha, Q^2)).
\]
(35)

It is plain that
\[
P_T(Q^2 = 0) = 1.
\]
(36)
so that at \(Q^2 = 0\) in the rainbow-ladder treatment of the interaction in Eq. (4) the dressed-quark-photon vertex is equal to the bare vertex. However, this is not true for \(Q^2 \neq 0\). Indeed, the transverse part of the dressed-quark-photon vertex will exhibit a pole at that \(Q^2 < 0\) for which
\[
1 + K_T(Q^2) = 0.
\]
(37)
This is just the model’s BSE for the ground-state vector meson. The mass obtained therefrom is listed in Table I.

In Fig. 1 we depict the function that dresses the transverse part of the quark-photon vertex. The pole associated with the ground-state vector meson is clear. Another important feature of the product rule. This emphasizes again that single-pole vector-meson-dominance is a helpful phenomenology but not a hard truth.

We show in Fig. 2 that dressing the quark-photon vertex does not qualitatively alter the behavior of \(F_{\pi}^\text{em}(Q^2)\) at spacelike momenta. In particular, it does not change the fact that a momentum-independent interaction, Eq. (4), regularized in a symmetry-preserving manner, produces
\[
F_{\pi}^\text{em}(Q^2 \to \infty) = \text{constant}.
\]
(39)

III. TRANSITION FORM FACTOR: \(\gamma^* \pi^0 \gamma\)

In the rainbow-ladder truncation this process is computed from [16]
\[
T_{\mu\nu}(k_1, k_2) = T_{\mu\nu}^\text{em}(k_1, k_2) + T_{\mu\nu}(k_2, k_1),
\]
(40)
where the pion’s momentum \(P = k_1 + k_2, k_1, k_2\) are the photon momenta, and
\[
T_{\mu\nu}(k_1, k_2) = \frac{\alpha_{\text{em}}}{\pi f_\pi} \epsilon_{\mu\nu\alpha\beta} k_{1\alpha} k_{2\beta} G(k_1^2, k_1 \cdot k_2, k_2^2)
\]
(41)
\[
= \text{tr} \int \frac{d^4 \ell}{(2\pi)^4} \chi_\pi(\ell_1, \ell_2) i Q \Gamma_\mu(\ell_2, \ell_1) \times S(\ell_1) i Q \Gamma_\nu(\ell_1, \ell_1),
\]
(42)
with \(\ell_1 = \ell - k_1, \ell_2 = \ell + k_2, \ell_12 = \ell - k_1 + k_2,\) and \(Q = \text{diag}[e_u, e_d]\). Owing to the vector Ward-Takahashi identity, the longitudinal part of the vertex does not contribute to the pion’s elastic form factor.

\[
k_1^2 = Q^2, \quad k_2^2 = 0, \quad 2k_1 \cdot k_2 = -(m^2 + Q^2).
\]
(43)
A. Anomaly

We first consider the chiral limit and $Q^2 = 0$, in which case Eq. (42) describes the “triangle diagram” that produces the Abelian anomaly and one must compute $G(0, 0, 0)$. We explained previously that our regularization of the interaction in Eq. (4) ensures that the nonanomalous vector and axial-vector Ward-Takahashi identities are satisfied. The outcome for the anomalous case is therefore very interesting.

Two contributions are obtained upon inserting Eq. (12) into Eq (42), viz., one associated with $E_*(P)$, which we will denote $G_E$, and the other with $F_*(P)$, to be called $G_F$. We first examine the latter. To obtain $G_F(0, 0, 0)$ one need only expand the integrand in Eq. (42) around $k_1 = 0 = k_2$ and keep the term linear in $F_*(P)k_{1\mu}k_{2\beta}$, a process that yields

$$G_F(0, 0, 0) = -\frac{f_\pi}{M} \int_0^\infty ds \sigma_\pi(s) F_*(P) \sigma_V(s) \times \left[ \sigma_V(s)^2 + s\sigma_V(s)\sigma_\nu'(s) + \sigma_\nu(s)\sigma_\nu'(s) \right].$$

where $\sigma_\nu'(s) = \frac{d}{ds}\sigma_\nu(s)$ and we have written

$$S(\ell) = -i\gamma \cdot \ell \sigma_V(\ell^2) + \sigma_\nu(\ell^2).$$

Using Eq. (6), one readily finds that $\sigma_\nu' = -\sigma_\nu^2, \sigma_\nu' = -M\sigma_\nu^2$. These identities, when inserted into Eq. (44), reveal that the integrand is identically zero, so that

$$G_F(0, 0, 0) = 0.$$  

This is a particular case of the general result proved in Ref. [14]. As explained therein, since the integral in Eq. (44) is logarithmically divergent, the result is only transparent with the choice of momentum partitioning that we employed.

The remaining contribution is $G_E$, which, following the methods of Sec. II, can be written

$$G_E(0, 0, 0) = \frac{M f_\pi}{\pi^2} \int d^4\ell \sigma_\pi(\ell^2) \sigma_V(\ell^2) \sigma_V(\ell^2).$$

The integral is convergent and therefore a shift in integration variables cannot affect the result. It follows that

$$G_E(0, 0, 0) = E_*(P) \frac{f_\pi}{M} \int_0^\infty dss \frac{M^2}{(s + M^2)^3}.$$  

If we employ Eq. (8), as with all other computations hitherto, this becomes

$$G_E(0, 0, 0) = \frac{1}{M^2} C_{\pi}(M^2),$$

where $C_{\pi}(z) = (z^2/2)(d^2/dz^2)C_{\pi}(z)$ and we used the Goldberger-Treiman relation in Eq. (30).

In what has long been a textbook result, the anomalous Ward-Takahashi identity states that $G_E(0, 0, 0) = \frac{1}{2}$; truly, just this simple fraction. Equation (49) is plainly inconsistent with this because it produces a number that depends on the values of the parameters $\Lambda_\pi, \Lambda_\nu$. Indeed, with the values in Eq. (27), our regularization of Eq. (4) gives $f_{\pi} G_E(0, 0, 0) = 0.36$. What has gone wrong?

The answer lies in the observation that

$$C_{\pi}(M^2) = C_2(M^2, r_{1\pi}^2 \rightarrow \infty, r_{1\nu}^2 \rightarrow 0) = \frac{1}{2} M^2.$$  

One could have judged at the outset that no regularization scheme that bounds the loop integral can supply the correct result for the anomalous Ward-Takahashi identity because it blocks the crucial connection between the anomaly, topology, and DCSB [39].

To elucidate, return to Eq. (48). The integral is convergent and dimensionless. Hence it cannot depend on $M$. In a particular application of the procedure elucidated in Refs. [10,12–14], the change of variables $C(s) = M/s$ yields

$$G_E(0, 0, 0) = \int_0^\infty dC \frac{1}{(1 + C)^3}$$

and the term linear in $F_*(P)$ becomes

$$G_F(0, 0, 0) = \frac{1}{2} \int_0^\infty dC \frac{d}{dC} \frac{1}{(1 + C)^2} = \frac{1}{2}.$$

B. Asymptotic behavior

1. Massless vector-boson exchange

In Ref. [40], using the methods of light-front quantum field theory, it was shown that

$$\lim_{Q^2 \rightarrow \infty} Q^2 G\left( Q^2, -\frac{1}{2} Q^2, 0 \right) = 4\pi^2 f_{\pi}^2.$$  

It is notable that this is a factor of $\pi/\alpha_s(Q^2)$ bigger than the kindred limit of the elastic pion form factor [40–42]; i.e., at $Q^2 = 4$ GeV$^2$, more than an order of magnitude larger.

Our analysis of Eq. (42) is performed within a Poincaré covariant formulation. In this case, as elucidated in Ref. [20], the asymptotic limit of the doubly off-shell process $(\gamma^* \gamma^* \rightarrow \pi^0)$ is reliably computable in the rainbow-ladder truncation because both quark legs in the dressed-quark-photon vertex are sampled at the large momentum scale $Q^2$, with the result [18,19]

$$\lim_{Q^2 \rightarrow \infty} Q^2 G\left( Q^2, -Q^2 - m_{\pi}^2/2, 0 \right) = \frac{2}{3} 4\pi^2 f_{\pi}^2,$$

if the propagator of the exchanged vector boson behaves as $1/k^2$ for large $k^2$. To obtain this result it is crucial that the pion’s Bethe-Salpeter amplitude depends on the magnitude of the relative momentum and behaves as $1/k^2$ for large $k^2$, as it does in QCD. (See also Sec. III.C.)

Equations (53) and (54) correspond to the asymptotic limits of different but related processes. Part of the mismatch owes to the fact that in the process $\gamma^* \gamma \pi^0$ not all quark legs attached to vertices carry the large momentum scale $Q^2$, namely $\ell_2^2$ in Eq. (42), and hence some amount of vertex dressing contributes, even at large $Q^2$. This is consistent with a more general observation; namely, that in a covariant calculation any number of loops contribute to $\gamma^* \gamma \pi^0$ at leading order [40] and these provide a series of logarithmic
corrections that should be summed. The same is true of the pion’s elastic form factor [14]. Nevertheless, the correct power-law behavior is necessarily produced.

2. Contact interaction

With the QCD-based expectation made clear, we now turn to the outcome produced by the contact interaction, Eq. (4). In this instance the arguments used to obtain Eq. (54) fail conspicuously because the pion’s Bethe-Salpeter amplitude is completely independent of the relative momentum; all values of the relative momenta are equally likely. This is why the interaction yields Eq. (39), a result in striking disagreement with experiment. A similar result is obtained in the present context. However, a decision must be made before that can be exhibited.

Recall Eqs. (44) and (48): the first is logarithmically divergent while the second is convergent even if the regularization parameters are removed. Indeed, one needs to remove the regularization scales if the anomaly value is to be recovered. However, the form factor is then ill defined because the term contributes the logarithmic divergence just noted. We proceed by removing the regularization in computing $G_F$, but retaining it in calculating $G_F$. Notably, as we will see, with Eq. (4) no internally consistent scheme can provide QCD-like ultraviolet behavior, but this prescription serves to preserve the infrared behavior.

There is one more step in implementing this scheme. In arriving at expressions such as those defining the pion’s Bethe-Salpeter kernel (see Sec. II D), we re-express a product of propagator denominators via a Feynman parametrization, then perform a change of variables, and thereafter rewrite the result using Eq. (8). This does not introduce any difficulties when the boundary at space-time infinity has no physical impact. However, as we have seen, that is not the case with the anomaly. The integral that defines $G_F$ is logarithmically divergent. A shift of integration variables changes its value, and in doing that one runs afoot of the fact that it is impossible to simultaneously preserve the vector and axial-vector Ward-Takahashi identities for triangle diagrams in field theories with axial currents that preserve the vector and axial-vector Ward-Takahashi identities [22,35].

In doing so we implement an anomaly-free electromagnetic current [43].

In Fig. 3 we depict the result produced from Eq. (4) using the regularizations just described. Comparing the solid and dashed curves, it is evident that the effect of dressing the quark-photon vertex diminishes with increasing $Q^2$ and therefore has no impact on the asymptotic behavior of the transition form factor. It does, however, affect the neutral-pion interaction radius, which can be defined via

$$r_{\pi^0}^2 = \frac{d}{d Q^2} \ln G[Q^2, -(m_\pi^2 + Q^2)/2, 0]|_{Q^2=0}. \quad (56)$$

This yields $r_{\pi^0}^2 = 0.30$ fm and $r_{\pi^0}^\rho = 0.45$ fm, values that are not sensibly distinguishable from the charged-pion values listed in Table I. Near equality of $r_{\pi^-}$ and $r_{\pi^0}$ is also found in the QCD-based calculations of Refs. [20,35].

More significantly, the solid and dashed curves in Fig. 3 show that, as with the elastic form factor [22], the presence of the pion’s necessarily nonzero pseudovector component $F_\gamma(P)$ leads to

$$\lim_{Q^2 \to \infty} G[Q^2, -(m_\pi^2 + Q^2)/2, 0] = \text{constant}. \quad (57)$$

This is consistent with the picture developed in Ref. [22]; namely, it is possible to treat the contact interaction, Eq. (4), so that it yields static properties of the pion in agreement with the experiment and computations based on well-defined and systematically improvable truncations of QCD’s DSEs. However, a marked deviation from the experiment occurs in processes that probe the pion with $Q^2 \lesssim M^2$ and it is impossible to obtain results that agree with perturbative QCD, even at the gross level of form-factor power laws.

These observations are emphasized by the comparisons presented in Figs. 4 and 5. The $\gamma^* \gamma \to \pi^0$ form factor obtained using the symmetry-preserving, fully self-consistent rainbow-ladder treatment of the contact interaction in Eq. (4) is in glaring disagreement with all existing data. This is what it means to have a pointlike component in the pion: all form factors must asymptotically approach a constant. That limit rapidly becomes apparent with increasing momentum transfer because the dynamically generated mass scale associated with low-energy hadron phenomena is $M \sim 0.4$ GeV. No study that neglects the pion’s pseudovector component can provide a valid explanation or interpretation of the $\gamma^* \gamma \to \pi^0$ transition form factor, or any other of the pion’s form factors.

[3]Choosing instead the $\gamma^* \gamma^* \to \pi^0$ form factor, one finds $r_{\pi^0}^\gamma = 0.44$ fm and $r_{\pi^0}^\rho = 0.55$ fm, values which are larger because the momentum scale $Q^2$ enters into both quark-photon vertices.
C. Pion distribution amplitude

It is worthwhile to consider a little further the nature of a pointlike pion. As explained in Ref. [44], with the dressed-quark propagator and pion Bethe-Salpeter amplitude in hand, one can compute the pion’s valence-quark parton distribution function in rainbow-ladder truncation. For the contact interaction, the result is

\[
q_V(x) = \frac{3}{2i} \int_{\mathbb{D}} d^4\ell \frac{F_{\pi}}{(2\pi)^4} \delta(n \cdot \ell - x n \cdot P) \times \Gamma_\pi(-P) S(\ell) n \cdot \gamma S(\ell) \Gamma_\pi(P) S(\ell - P),
\]

where \( n^2 = 0, n \cdot P = P^+, \) and \( x \) is the Bjorken variable.

It follows from this expression that

\[
(n \cdot P)^{n+1} \int_0^1 dx^n q_V(x) = \frac{3}{2i} \int_{\mathbb{D}} d^4\ell \frac{F_{\pi}}{(2\pi)^4} (n \cdot \ell)^n \Gamma_\pi(-P) \times S(\ell) n \cdot \gamma S(\ell) \Gamma_\pi(P) S(\ell - P).
\]

At this point we’ll specialize to the chiral limit and evaluate the Dirac-trace; use a Feynman parametrization to re-express the product \( \sigma_V(\ell^2)q_V(\ell^2) \) that arises; shift variables \( \ell \rightarrow (\ell + \alpha P) \), where \( \alpha \) is the Feynman parameter; use the \( O(4) \) invariance of the measure to evaluate the angular integrals; and thereby arrive at

\[
\int_0^1 dx^n q_V(x) = \frac{1}{n+1} \left[ \frac{3}{4\pi^2} \left( \frac{M^2}{F_{\pi}} \right)^2 E_\pi - 2F_\pi \right]
\]

where the last line follows because the pion’s Bethe-Salpeter amplitude is canonically normalized, Eq. (26).

The distribution function is readily reconstructed from Eq. (60); and one finds that even with the inclusion of the pion’s necessarily nonzero pseudovector component, the contact interaction produces

\[
q_V(x) = \theta(x)\theta(1-x),
\]

which corresponds to a pion distribution amplitude

\[
\phi_\pi(x) = \text{constant}.
\]

This outcome provides another way of understanding the inability of the contact interaction to reproduce the results of QCD.

As reviewed and explained in Ref. [44], Goldstone’s theorem in QCD is expressed in a remarkable correspondence between the quark-propagator and the pion’s Bethe-Salpeter amplitude (i.e., between the one-body and two-body problems [32]). The long-known fact that the dressed-quark mass function behaves as \([45-49]\)

\[
M(p^2) \propto \frac{1}{p^2},
\]

entails that in QCD every scalar function in the pion’s Bethe-Salpeter amplitude, Eq. (1), depends on the relative momentum \( k \) as \( \sim 1/k^2 \) for large \( k^2 \) (with additional logarithmic suppression). It is impossible to find a kinematic arrangement of the dressed quarks constituting the pion in
which the Bethe-Salpeter amplitude remains nonzero in the limit of infinite relative momentum.

It follows that in QCD the pion’s valence-quark distribution behaves as \((1 - x)^{x+y}, 0 < y \ll 1\), for \(x \rightarrow 1\), at a renormalization scale of 1 GeV [44,50]. Hence there is no renormalization scale in the application of perturbative QCD at which Eq. (61) is a valid representation of nonperturbative QCD dynamics; namely, no scale at which it is tenable to employ \(\phi(x) = \text{constant}\), or even, more weakly, flat and nonzero at \(x = 0, 1\).

### IV. REFLECTIONS ON EXTANT DATA

We showed that an internally consistent treatment of the contact interaction is incompatible with extant pion elastic (Fig. 2) and transition form factor data (Figs. 4 and 5). Notwithstanding this, the results elucidated can be used in combination with QCD-based DSE studies to comment on available data for the process \(\gamma^*\gamma \rightarrow \pi^0\).

To begin we remark upon a similarity between the \(Q^2\) dependence of the dash-dot and dotted curves in Fig. 3 (i.e., the QCD-based DSE result and that obtained from the contact interaction if the pion’s pseudovector component is artificially eliminated). We emphasize that if \(F_\pi(P)\) is forced to zero, then one is no longer representing faithfully the features and consequences of a vector-vector contact interaction. Hitherto, this has nevertheless been a conventional mistreatment of the QCD-based DSE result and that obtained from the contact interaction if the pion’s pseudovector component is artificially eliminated. We emphasize that if \(\phi_\pi(x)\) is fully self-consistent treatments of pion static properties, and elastic and transition form factors, the asymptotic limit of the product \(Q^2G_{\gamma^*\gamma\pi^0}(Q^2)\), which is determined \textit{a priori} by the interaction employed, is not exceeded at any finite value of spacelike momentum transfer. The product is a monotonically increasing concave function. Indeed, this is even true of the solid curve in Fig. 5.

Below. Stated differently, each is a monotonically increasing concave function. Indeed, this is even true of the solid curve in Fig. 5.

### V. CONCLUSION

We showed that in fully self-consistent treatments of pion static properties, and elastic and transition form factors, the asymptotic limit of the product \(Q^2G_{\gamma^*\gamma\pi^0}(Q^2)\), which is determined \textit{a priori} by the interaction employed, is not exceeded at any finite value of spacelike momentum transfer. The product is a monotonically increasing concave function. We understand a consistent approach to be one in which a given quark-quark scattering kernel is specified and solved in a well-defined, symmetry-preserving truncation scheme; the interaction’s parameter(s) are fixed by requiring a uniformly good description of the pion’s static properties; and the relationships between computed quantities are faithfully maintained.

Within such an approach it is nevertheless possible for \(Q^2F_{\pi}^\text{em}(Q^2)\), with \(F_{\pi}^\text{em}(Q^2)\) being the elastic form factor, to exceed its asymptotic limit because the leading-order matrix element involves two Bethe-Salpeter amplitudes. This permits an interference between dynamically generated infrared mass scales in the computation. Moreover, for \(F_{\pi}^\text{em}(Q^2)\) the perturbative QCD limit is more than an order of magnitude smaller than \(m_\rho^2\). Owing to the proximity of the \(\rho\)-meson pole to \(Q^2 = 0\), the latter mass scale must provide a fair first estimate for the small-\(Q^2\) evolution of \(F_{\pi}^\text{em}(Q^2)\). A monopole based on this mass scale exceeds the pQCD limit \(\forall Q^2 > 0\). For the transition form factor, however, the opposite is true because \(m_\rho^2\) is less than the pQCD limit, Eq. (53).
A vector-current-current contact-interaction may be described as a vector-boson exchange theory with vector-field propagator (1/k^2)^r, r = 0. We showed (see Figs. 4 and 5) that the consistent treatment of such an interaction produces a γ*γ → π^0 transition form factor that disagrees with all available data. However, precisely the same treatment of an interaction that preserves the one-loop renormalization group behavior of QCD produces a form factor in good agreement with all but the large-Q^2 data from the BaBar Collaboration [1].

Studies exist that interpret the BaBar data as an indication that the pion’s distribution amplitude φπ(x) deviates dramatically from its QCD asymptotic form, indeed, that φπ(x) = constant, or is at least flat and nonvanishing at x = 0, 1 [51, 52]. We have explained that such a distribution amplitude characterizes an essentially pointlike pion; and shown that, when used in a fully consistent treatment, it produces results for pion elastic and transition form factors that are in striking disagreement with experiment. A bound-state pion with a pointlike component will produce the hardest possible form factors; i.e., form factors that become constant at large Q^2.

On the other hand, QCD-based studies produce soft pions, a valence-quark distribution amplitude for the pion that vanishes as ~((1 - x)^2) for x → 1, and results that agree well with the bulk of the existing data.

Our analysis shows that the large-Q^2 BaBar data are inconsistent with QCD and also inconsistent with a vector current-current contact interaction. It supports a conclusion that the large-Q^2 data reported by BaBar are not a true representation of the γ*γ → π^0 transition form factor, a perspective also developed elsewhere [53]. We are confirmed in this view by the fact that the γ* → ηγ and γ* → η′γ transition form factors have also been measured by the BaBar Collaboration [54], at Q^2 = 112 GeV^2, and in these cases the results from CLEO [3] and BaBar are fully consistent with perturbative QCD expectations.
