Abstract: We quantify uncertainties in the Monte-Carlo simulation of inclusive and dijet final states, which arise from using the MC@NLO technique for matching next-to-leading order parton level calculations and parton showers. We analyse a large variety of data from early measurements at the LHC. In regions of phase space where Sudakov logarithms dominate over high-energy effects, we observe that the main uncertainty can be ascribed to the free parameters of the parton shower. In complementary regions, the main uncertainty stems from the considerable freedom in the simulation of underlying events.

1 Introduction

QCD jet production constitutes an important background in a variety of searches for theories beyond the Standard Model [1–6]. At the same time, measurements of inclusive jet and dijet cross sections are used to constrain parton distributions [7–9] and to determine the value of the strong coupling [10–12]. Despite the tremendous importance of QCD jet production, precise predictions of event rates and kinematics using higher-order perturbation theory remain challenging. Only up to four-jet final states have been computed at the next-to-leading order so far [13–20]. Phenomenologists therefore typically rely on the simulation of high-multiplicity signatures by Monte-Carlo event generators.

The ATLAS and CMS experiments at the CERN Large Hadron Collider have recently measured inclusive jet and dijet production [21–27], with many observables implicitly probing higher-order effects. The outstanding quality of these data allows to validate and refine existing Monte-Carlo tools. The scope of this publication is a quantification of related perturbative and non-perturbative uncertainties.

Calculating next-to-leading order QCD corrections to arbitrary processes has become a highly automated procedure, limited only by the capacity of contemporary computing resources. Infrared subtraction techniques [28–30] are implemented by several general-purpose matrix element generators [31–35]. The computation of virtual corrections is tackled by a variety of dedicated programs [36–51]. Turning the parton level result into a prediction at the particle level then requires a matching to the parton shower in order to implement resummation. Two methods have been devised to perform this matching procedure, the MC@NLO [52] and the POWHEG [53, 54] technique. While both are formally correct at the next-to-leading order, they
exhibit subtle differences, which have been in the focus of interest recently [55,56]. We shall continue this study to some extent and perform a detailed comparison of scale uncertainties with resummation uncertainties as well as ambiguities arising from the Monte-Carlo simulation of the underlying event. We will employ the MC@NLO technique to match next-to-leading order parton-level results for dijet production with the parton shower as implemented in the event generator SHERPA [57,58]. Virtual corrections are obtained from the BLACKHAT library [20,41,59]. Earlier studies of inclusive jet and dijet production used the POWHEG approach [60]. They exhibit a large dependence on the parton-shower and underlying-event model [21]. We expect that the conclusions drawn from our study will also apply to the simulation provided in [60], as the MC@NLO and POWHEG techniques are of the same formal accuracy.

The outline of this paper is as follows: Section 2 introduces the theoretical framework for our study, including a description of the new developments in SHERPA, which allow to perform the variation of scales in a manner consistent with analytical resummation techniques. Section 3 presents results and discusses the size and relative importance of the various types of uncertainties. Section 4 contains some concluding remarks.

2 The MC@NLO matching method and its uncertainties

This section outlines the essence of the MC@NLO technique for matching next-to-leading order matrix elements and parton showers. We follow the notation introduced in [55] and report on an extension of the MC@NLO implementation therein, which allows to vary resummation scales in a more meaningful way. We point out the free parameters of the MC@NLO method, which will be used to obtain quantitative predictions in Sec. 3.

Notation

In the following, B(ΦB) will be used to label Born squared matrix elements, defined on the Born phase space ΦB, which are summed/averaged over final-/initial-state spins and colours and include parton luminosities as well as symmetry and flux factors. Squared matrix elements of real emission corrections are denoted by R(ΦR). They are defined on the real-emission phase space ΦR. Virtual corrections, including collinear counterterms, are denoted by V. Real and virtual corrections induce infrared singularities of opposite sign, which cancel upon integration [61,62]. In order to exploit this cancellation for the construction of Monte-Carlo event generators, subtraction formalisms are invoked [28,29], which introduce real subtraction terms D(S)ij,k and their corresponding integrated counterparts I(S)ij,k.

In the MC@NLO method, one defines additional Monte-Carlo counterterms, D(A)ij,k, which represent the evolution kernels of the resummation procedure. These counterterms must necessarily have the correct infrared limit in order for the method to maintain full NLO accuracy [55]. Therefore, full colour and spin information needs to be retained. Ordinary parton-shower evolution kernels are recovered from the MC counterterms by taking the limit Nc → ∞ and averaging over spins.

Away from the collinear limit, the form of MC counterterms is less constrained, which essentially presents a source of uncertainty of the MC@NLO method. This particular uncertainty will not be addressed here as it can be reduced by matrix-element parton-shower merging at the next-to-leading order [63,65].

It is particularly useful to identify the MC counterterms with infrared subtraction terms, D(A)ij,k = D(S)ij,k, up to phase space constraints. This procedure was advocated in [55], but the corresponding implementation suffered from unknown integrals in the integrated subtraction terms in the case that the phase-space was parametrised in terms of parton-shower evolution and splitting variable. In this publication, the problem is solved by performing the integral of the remainder term D(A)ij,k − D(S)ij,k numerically.
The MC@NLO method

In terms of the above defined quantities, omitting flavour- and phase-space mappings, the expectation value of an arbitrary infrared safe observable \( O \) in the MC@NLO method is given by [52]

\[
\langle O \rangle = \int d\Phi_B \, B^{(A)}(\Phi_B) \left[ \Delta^{(A)}(t, \mu_Q^2) \, O(\Phi_B) + \sum_{\{ij,k\}} \int d\Phi_{R|B}^{ij,k} \, \frac{D^{(A)}_{ij,k}(\Phi_B, \Phi_{R|B}^{ij,k})}{B(\Phi_B)} \, \Delta^{(A)}(t, \mu_Q^2) \, O(\Phi_R) \right]
\]

\[ + \int d\Phi_R \left[ R(\Phi_R) - \sum_{ij,k} D^{(A)}_{ij,k}(\Phi_R) \, \Theta(\mu_Q^2 - t) \right] \, O(\Phi_R) . \tag{2.1} \]

Therein, Born phase space configurations \( \Phi_B \) are assigned next-to-leading order weights according to

\[
B^{(A)}(\Phi_B) = B(\Phi_B) + \tilde{V}(\Phi_B) + \sum_{\{ij,k\}} I^{(S)}_{ij,k}(\Phi_B)
\]

\[ + \sum_{\{ij,k\}} \int d\Phi_{R|B}^{ij,k} \left[ D^{(A)}_{ij,k}(\Phi_B, \Phi_{R|B}^{ij,k}) \, \Theta(\mu_Q^2 - t) - D^{(S)}_{ij,k}(\Phi_B, \Phi_{R|B}^{ij,k}) \right] . \tag{2.2} \]

The real-emission phase space associated with parton emission off an external leg \( \tilde{i}j \) of the Born configuration \( \Phi_B \) can be factorised as \( \Phi_R = \Phi_B \cdot \Phi_{R|B}^{ij,k} \). In this context, \( k \) denotes spectator partons in the splitting \( \tilde{i}j, \tilde{k} \rightarrow i, j, k \), which are used to absorb the recoil when a splitting parton \( \tilde{i}j \) is put on-shell in the subtraction procedure. The emission phase space, \( d\Phi_{R|B}^{ij,k} \), can be parametrised as \( d\Phi_{R|B}^{ij,k} \propto dt \, dz \, d\phi \), i.e. in terms of an evolution variable \( t \), a splitting variable \( z \) and an azimuthal angle \( \phi \). The evolution variable \( t \) is usually identified with some transverse momentum, \( k_t^2 \). In the above equations, we always assume \( t = t(\Phi_{R|B}^{ij,k}) = t(\Phi_R, \Phi_B) \).

We call Eq. (2.2) the next-to-leading order weighted Born cross section. The sum over parton configurations and the integral over the emission phase space in Eq. (2.2) are both evaluated using Monte-Carlo methods, while keeping the Born phase space point, \( \Phi_B \), fixed. Because of the choice \( D^{(A)}_{ij,k} = D^{(S)}_{ij,k} \), the integrand varies only mildly. A single phase-space point is therefore sufficient to obtain a reliable estimate of the integral. Note that in [55] the corresponding integral was absent as the phase-space constraints on \( D^{(A)}_{ij,k} \) were chosen to be the same as on \( D^{(S)}_{ij,k} \). While this method lead to fewer fluctuations of the MC integral, it severely restricted the flexibility of the MC@NLO and hampered the correct assessment of uncertainties. In this publication we are able to lift this restriction while still maintaining full next-to-leading order accuracy of the simulation through incorporating full colour and spin information in the resummation.

The resummation procedure itself is encoded in the square bracket multiplying the NLO-weighted Born matrix element, \( B^{(A)} \), on the first and second line of Eq. (2.1). Note that the square bracket is unitary by construction. The overall Sudakov factor \( \Delta^{(A)} \) is defined as

\[
\bar{\Delta}^{(A)}(t, t') = \prod_{\{ij,k\}} \bar{\Delta}^{(A)}_{ij,k}(t, t') , \tag{2.3} \]

with the partial Sudakov factors given by

\[
\bar{\Delta}^{(A)}_{ij,k}(t, t') = \exp \left\{ - \sum_{i=q,g} \int d\Phi_{R|B}^{ij,k} \frac{1}{S_{ij}} \frac{S_R}{S_B} \frac{D^{(A)}_{ij,k}(\Phi_B, \Phi_{R|B}^{ij,k})}{B(\Phi_B)} \right\} . \tag{2.4} \]

Again, \( t = t(\Phi_{R|B}^{ij,k}) \) is implied and the dependence of the Sudakov factor on the Born phase space configuration is implicit. This Sudakov factor differs from the ordinary parton-shower Sudakov by including full colour and spin correlations. Its implementation is detailed in [55]. The factors \( S_B \), \( S_R \) and \( S_{ij} \) account for the potentially different symmetry factors present in the Born and real-emission matrix elements and the
parton-shower expression, respectively. In the latter, identical particles produced at different scales \( t \) are distinguishable, leading to a factorisation of symmetry factors along the evolution chain. The third line in Eq. (2.1) encodes the non-logarithmic remainder terms of the next-to-leading order real-emission correction. Subsequent parton-shower evolution is effected on both terms respecting the emission scales already present. If necessary, truncated parton-shower emission are inserted \[53\] to retain the logarithmic accuracy of the parton shower.

### Uncertainties

The evolution variable in the Monte-Carlo counterterms is limited from above by the resummation scale squared, \( \mu_Q^2 \). This scale was introduced in the context of analytic resummation \[66\]-\[70\]. It can be used to assess the uncertainties associated with the resummation programme. We will make extensive use of this possibility in Sec. \[6\]

When defining scales for different parts of the calculation, there are certain restrictions that have to be adhered to. In principle, both the factorisation scale, \( \mu_F \), and the renormalisation scale, \( \mu_R \), in the NLO weighted Born ME and the hard remainder function can be chosen freely. The difference induced by different scales is formally of \( \mathcal{O}(\alpha_s^2) \) relative to the Born contribution. It can, however, have a sizable impact in practice.

A different scale can be chosen for the resummation kernel in the square bracket of Eq. (2.1), which corresponds to the scale employed by the parton shower. This scale is required to be consistent with the one used in the shower itself. In order to achieve full next-to-logarithmic accuracy, it must be of the functional form of the relative transverse momentum of the splitting, \( k_{\perp} \), as \( k_{\perp} \to 0 \) \[71\].

Additional uncertainties arise from subsequent parton showers, hadronization and the simulation of multiple parton scattering. We comment on these effects in the following section.

### 3 Results

In this section results generated with the MC@NLO algorithm detailed previously are presented for inclusive jet and dijet production. Monte-Carlo predictions are compared to a wide variety of measurements made by both the ATLAS and CMS experiments at the LHC at 7 TeV. The automated implementation of the MC@NLO algorithm in the Monte-Carlo event generator SHERPA, detailed in \[55\], is used where the only non-automated ingredient, the one-loop matrix element, is interfaced from BLACKHAT \[15\]-\[20\] employing the methods of \[72\]. Further QCD evolution is effected using SHERPA’s built-in CSS parton shower \[73\]. Non-perturbative corrections, including multiple parton interactions \[74\], hadronization corrections \[75\]-\[76\] and hadron decays \[77\], are calculated using phenomenological models tuned to data. The standard tune for SHERPA-1.4.0 has been used. Soft-photon corrections are simulated using \[78\]. The CT10 parton distribution functions \[79\] have been employed throughout. All results are presented at the particle level, using only stable final state particles with a lifetime longer than 10 ps.

For the central theoretical prediction the scales have been chosen as

\[
\mu_F = \mu_R = \frac{1}{2} H_T \quad \text{and} \quad \mu_Q = \frac{1}{2} p_{\perp}.
\]

Therein, \( H_T \) is defined as the sum of the scalar transverse momenta of the jets found in the partonic process before applying any resummation. These partonic jets are defined using the anti-\( k_{\perp} \) algorithm \[80\]-\[81\] with \( R = 0.4 \) and \( p_{\perp}^{\min} = 20 \) GeV. \( p_{\perp} \) is the transverse momentum of any of the two jets of the Born phase space configuration upon which the MC@NLO procedure is effected. To estimate the intrinsic uncertainty of the predictions the perturbative scales \( \mu_F \) and \( \mu_R \) have been varied independently by the conventional factor of 2 around the central scale while the resummation scale is kept fixed. For the resummation scale variation, taking into account the simple form of the exponent of the Sudakov factor, the prescription of \[67\] is followed, varying \( \mu_Q \) by a factor of \( \sqrt{2} \) around the central choice while both \( \mu_F \) and \( \mu_R \) are kept fixed.

Further, non-perturbative uncertainties, i.e. the impact of shortcomings of the phenomenological models, have been assessed following the prescription outlined in \[52\]: Alternative tunes increasing and decreasing the mean charged multiplicity in the transverse region by 10% were used to estimate the uncertainty in the multiple parton interaction model\[1\]. Exchanging the cluster hadronization model of \[75\]-\[76\] for the Lund

---

1 This corresponds to changing the switch \( \text{SIGMA_ND\_FACTOR} \pm 0.03 \) (increase/decrease) around the central tune value.
string hadronization model \[83\] has been found to have negligible impact on jet observables in previous studies \[55,82\], and is therefore not considered here.

All observables studied in the following have been calculated using the same event sample. It is defined by requiring at least two anti-\(k_t\) jets (\(R = 0.4\)) with \(p_T > 10\) GeV at the parton level before applying any resummation, of which at least one must have \(p_T > 20\) GeV. Fig. 1 presents the colour scheme used to display the individual uncertainties and their overlaps.

Inclusive jet rates

The first observables to study are inclusive jet production rates. These have been measured by the ATLAS collaboration \[21\]. Jets are defined at the particle level using the anti-\(k_t\) algorithm with \(R = 0.4\) and \(p_T > 60\) GeV within \(|y| < 2.8\). Jets are ordered in transverse momentum. Additionally, the leading jet is required to have \(p_T > 80\) GeV.

Fig. 2 presents the results. We observe good agreement between our Monte-Carlo simulations and experimental data. The renormalisation and factorisation scale uncertainty amounts to approximately 7% for the dijet inclusive cross-section, which is described at next-to-leading order accuracy, while it increases to 14% for the three-jet inclusive rate, which is described at leading order accuracy only. All higher multiplicity jet inclusive rates are described at the logarithmic accuracy of the parton shower only and therefore inherit the scale uncertainty of the inclusive three-jet rate. The resummation uncertainties, indicating the observables sensitivity to multiple higher-order soft emissions below the resummation scale, is slightly larger: 8% for the dijet inclusive cross section and 35% for the three-jet inclusive rate. They steadily increase for higher jet multiplicities. The non-perturbative uncertainties, on the other hand, are negligible, contributing from \(\sim 0.2\%\) for the dijet cross section to \(\sim 6\%\) for the inclusive 5 jet cross section.
Figure 3: Jet transverse momenta compared to ATLAS data [21].

Figure 4: Scalar sum of jet transverse momenta compared to ATLAS data [21].
The next observable to be examined is the relative rate of inclusive three-jet events compared to inclusive two-jet events. The CMS collaboration measured this ratio in dependence on the scalar sum of all jet transverse momenta, \( H_{T} \). \[ (2) \] Within this analysis events with at least two and three jets, respectively, defined with the anti-\( k_{T} \) algorithm with \( R = 0.5 \), \( p_{T} > 50 \text{ GeV} \), \( |y| < 2.5 \), and \( H_{T} > 0.2 \text{ TeV} \) were selected. The 3-jet over 2-jet ratio is then defined as \( R_{32} = \left( \frac{d\sigma \geq 3\text{jet}}{dH_{T}} \right) \left/ \left( \frac{d\sigma \geq 2\text{jet}}{dH_{T}} \right) \right. \). The comparison of the presented calculation to data is shown in the left panel of Fig. 5. Good agreement between MC predictions and data is observed. The scale variations in calculating \( \left( \frac{d\sigma \geq 3\text{jet}}{dH_{T}} \right) \), described at leading order, and \( \left( \frac{d\sigma \geq 2\text{jet}}{dH_{T}} \right) \), described at next-to-leading order, were done simultaneously because both observables were calculated from the same event sample. Consequently, the renormalisation and factorisation scale uncertainty are large at small \( H_{T} \) but largely cancel at large \( H_{T} \). The resummation uncertainty behaves similarly, but shows an opposite asymmetry at small \( H_{T} \). The non-perturbative uncertainties are much smaller for small \( H_{T} \) but grow to equivalent size in the large-\( H_{T} \) region.

The analysis of [21] also studied the 3-jet over 2-jet ratio both as a function of the the scalar transverse momentum sum of the two leading jets, \( H_{T}^{(2)} \), and as a function of the transverse momentum of the leading jet, \( p_{T}^{\text{had}} \). The results are displayed in the right panel of Fig. 5 and in Fig. 6, respectively. Both analyses show the same level of agreement between MC predictions and data. Scale uncertainties and non-perturbative uncertainties are of similar size as in the CMS analysis.
3 jets over 2 jets ratio for different minimum $p_{T}^{\text{jet}}$ (anti-kt R=0.4) 

**Figure 6:** 3-jet over 2-jet ratio in dependence on the leading jet transverse momentum in comparison to ATLAS data [21].

Jet azimuthal decorrelation in various $p_{T}^{\text{lead}}$ bins 

**Figure 7:** Azimuthal decorrelations of the leading jets compared to CMS data [25]. The individual $p_{T}^{\text{lead}}$ ranges on the left-hand side plot are ordered as indicated in the right-hand side ratio plots.
Figure 8: Inclusive jet transverse momenta spectra different rapidity ranges compared to ATLAS data [22].

The different rapidity ranges on the left-hand side plot are ordered as indicated in the right-hand side ratio plots, being multiplied, from top to bottom by factors of 1, 3, 10^{-2}, 10^{-3}, 10^{-5}, 10^{-6}, 3, 10^{-8}, and 10^{-9}, for readabilities sake.

Azimuthal decorrelations

Next, the correlations between the two leading jets are examined. The CMS collaboration measured the dijet azimuthal decorrelations, i.e. the $\Delta \phi$ separation of the two leading jets, in [25]. Therein, the jets are defined using the anti-$k_T$ jet algorithm with $R = 0.5$ and a minimum transverse momentum of $p_T > 30$ GeV within a rapidity interval of $|y| < 1.1$. Events with at least two such jets were classified according to the leading jet’s transverse momentum into five mutually exclusive regions: $p_T^{\text{lead}} \in [80, 110]$ GeV, [110, 140] GeV, [140, 200] GeV, [200, 300] GeV, and [300, $\infty$] GeV. The present calculation provides next-to-leading order accuracy at $\Delta \phi = \pi$, leading order accuracy in the region $\pi/2 < \Delta \phi < \pi$, and leading logarithmic accuracy in the region $\Delta \phi < \pi/2$. The results are shown in Fig. 7. Good agreement between data and MC prediction is found. The renormalisation and factorisation scale uncertainties are accordingly small in the region $\Delta \phi > \pi/2$ and increase towards lower $\Delta \phi$ values. Varying the resummation scale leads to similarly large uncertainties, while non-perturbative uncertainties only play a minor role. However, by normalising the observable to the inclusive dijet cross section, the scale uncertainties are artificially reduced.

Inclusive jet transverse momenta in different rapidity ranges

To further study correlations between multiple jets produced, it is useful to consider double-differential observables studied by the ATLAS collaboration [22]. We start with the inclusive jet transverse momentum in different rapidity ranges. Jets are defined using the anti-$k_T$ jet algorithm with $R = 0.4$, $p_T > 20$ GeV and $|y| < 4.4$. Every jet is considered in the analysis. The contribution from the first two jets in the region where at least two jets are present is described at next-to-leading order accuracy, while the contribution of a possible third jet is described at leading order. All contributions of subsequent jets are described at leading logarithmic accuracy only. Thus, the overall accuracy of these observables is a mixture of the above.
Dijet invariant mass spectra in different rapidity ranges

Figure 9: Dijet invariant masses in different rapidity ranges compared to ATLAS data. The rapidity differences are displayed in the left-hand side plot, where the variation is compared to ATLAS data. The rapidity differences are displayed in the right-hand side ratio plots, being multiplied, from top to bottom by factors of 10^{12}, 10^{10}, 10^{9}, 10^{8}, 10^{7}, 10^{6}, 10^{5}, 30, and 1, for readabilities sake.

Fig. 8 shows the result of the presented calculation compared to data. The agreement in all but the most forward rapidity ranges is good. Renormalisation and factorisation scale uncertainties are small for central jet production while they grow larger with increasing rapidity. The resummation scale uncertainty behaves similarly albeit being larger in magnitude throughout. Non-perturbative uncertainties are small, except in the very forward region, close to the beams. At very large rapidities the transverse momentum is no longer a good measure of the hardness of the process. Instead a scale taking into account the dijet invariant mass should be used. Such consideration applied to an $H_T$-based scale, taking into account real emission dynamics, is proposed to take the following form

$$\mu_{R/F} = \frac{1}{2} H_T^{(y)} = \frac{1}{2} \sum_{i \in \text{jets}} |p_{i,T}| e^{f \cdot |y-y_{\text{boost}}|}$$

(3.1)

wherein $y_{\text{boost}} = 1/n_{\text{jet}} \cdot \sum_{i \in \text{jets}} y_i$, the rapidity of the $n$-jet system. The factor $f$ is chosen to suitably interpolate between the invariant-mass-like behaviour and transverse-momentum-like behaviour. For $f = 0.3$ and the presence of only two jets it reduces exactly to the scale proposed in $H_T^{(y)} = \frac{1}{2} p_T e^{0.3y} \approx m_{12}/(4 \cosh(0.7y^*))$. This scale choice, however, is only beneficial for describing data in this and the following analysis and either shows no impact or even reduces the agreement with the observed experimental data in all other analyses considered in this publication. It is therefore not adopted as a central scale choice.

Dijet invariant masses in different rapidity ranges

Another doubly differential observable studied in is the dijet invariant mass. Events with at least two anti-$k_T$ jets with $R = 0.4$ and $p_T^{\text{lead}} > 30$ GeV and $p_T^{\text{sublead}} > 20$ GeV within $|y| < 4.4$ are considered.

Taking $\mu_{R/F} = \frac{1}{2} H_T^{(y)}$ as the central scale leads to an underestimate of the inclusive three-jet rate presented in Fig. 2 by 30%, for example.
The dijet invariant mass is defined \( m_{12} = \sqrt{(p_{\text{lead}} + p_{\text{sublead}})^2} \) and binned into various mutually exclusive ranges of \( y^* = \frac{1}{2} |y_{\text{lead}} - y_{\text{sublead}}| \), the rapidity separation of the two jets. Fig. 9 displays MC results compared to ATLAS data. For small rapidity separations the agreement with data is good. At large \( y^* \) the renormalisation and factorisation scale is too low, resulting in too large MC predictions. This situation is improved by choosing the scale Eq. (3.11) instead. The renormalisation and resummation scale uncertainties are small at small \( \Delta y \) and increase towards larger \( y^* \). They also remain approximately constant over the whole considered \( m_{12} \) range. Resummation scale uncertainties, on the other hand, are larger and display a definite \( m_{12} \) dependence. This can be seen as an indication that high-energy resummation, which goes beyond the collinear limit used in the parton shower, becomes important [85–87]. Non-perturbative uncertainties are only non-negligible at low invariant masses or large rapidity separations, when at least one jet is likely to be close to either of the two beams.

As discussed in the previous paragraph, taking \( \frac{1}{2} H_T^{(p)} \) as the central scale improves the description of this observable but leads to a worse description of the other observables investigated in this paper. It is therefore not adopted as the central scale.

**Gap fractions**

A different way to probe the radiation pattern was explored by the ATLAS collaboration in [23]. Therein, events were selected containing at least two jets, defined using the anti-\( k_T \) algorithm with \( R = 0.6 \), each with \( p_{\perp} > 20 \text{ GeV} \) within \( y < 4.4 \). Within these events a dijet system is then identified using either the two largest transverse momentum jets (leading jet selection) or the widest separated jets (forward backward selection). For both definitions an average transverse momentum \( \bar{p}_{\perp} = \frac{1}{2}(p_{\perp}^{\text{jet1}} + p_{\perp}^{\text{jet2}}) \) of at least 50 GeV is required. To characterise the subsequent radiation pattern two variables are used. The gap fraction, i.e. the fraction of events that do not exhibit any further radiation above some \( Q_0 \) within the \( \Delta y \) rapidity range spanned by the dijet system, and the mean number of jets with \( p_{\perp} > Q_0 \) in the same \( \Delta y \) region. Fig. 10 displays a comparison of MC results with data for the gap fraction \( (Q_0 = 20 \text{ GeV}) \) in dependence on the rapidity separation of the dijet system and its \( \bar{p}_{\perp} \) for both selections. The agreement is good throughout the probed region. In both selections the renormalisation and factorisation scale uncertainty is the leading uncertainty at low \( \bar{p}_{\perp} \) while the resummation uncertainty dominates at large \( \bar{p}_{\perp} \). Non-perturbative uncertainties are generally larger than for most other observables considered in this paper, increasing with \( \Delta y \) and \( \bar{p}_{\perp} \). In case of the forward backward selection they are of the same magnitude as both perturbative uncertainties in the large \( \Delta y \) and \( \bar{p}_{\perp} \) region.

Similarly, Fig. 11 displays the average number of jets \( (Q_0 = 20 \text{ GeV}) \) in dependence on the rapidity separation of the dijet system and its \( \bar{p}_{\perp} \) for both selections. Again, good agreement is found. All uncertainties are small and of comparable size for small \( \Delta y \) throughout the \( \bar{p}_{\perp} \) range, and steadily increasing for larger \( \Delta y \). While a resummation scale variation produces largely \( \bar{p}_{\perp} \) independent uncertainties the renormalisation and factorisation scale uncertainties are larger for small average transverse momenta than for large ones. The non-perturbative uncertainties show the opposite behaviour.

**Event shapes**

Traditional observables not being described without resummation are event shapes. The CMS collaboration measured the central transverse thrust and the central transverse thrust minor in multijet production in [26]. The sample is defined by requiring at least two jets, defined using the anti-\( k_T \) algorithm with \( R = 0.5 \), \( p_{\perp} > 30 \text{ GeV} \) and \( |y| < 1.3 \). The selected events are then categorised into three mutually exclusive regions according to the leading jet transverse momentum. The observables are defined as follows

\[
\tau_{1, C} = 1 - \frac{\sum_{i \in \text{jets}} |\vec{p}_{\perp,i} \cdot \hat{n}_T|}{\sum_{i \in \text{jets}} |\vec{p}_{\perp,i}|}
\]

and

\[
T_{m, C} = \frac{\sum_{i \in \text{jets}} |\vec{p}_{\perp,i} \times \hat{n}_{T, C}|}{\sum_{i \in \text{jets}} |\vec{p}_{\perp,i}|}.
\]

Therein, the vector \( n_T, C \) is defined as the vector minimising \( \tau_{1, C} \). Only jet momenta are taken into account. The results of the presented calculation are compared to the experimental data in Fig. 12. Good agreement between MC predictions and data is found. The dependence of both observables on the renormalisation and factorisation scale, despite being calculated at most at leading order accuracy, largely cancels due to their normalisation. However, they do show a large dependence on the resummation scale, as expected. This
Inclusive jet transverse momenta in different rapidity ranges

**Gap Fraction**

- $240 \text{ GeV} < p_{T} < 270 \text{ GeV}$
- $210 \text{ GeV} < p_{T} < 240 \text{ GeV}$
- $180 \text{ GeV} < p_{T} < 210 \text{ GeV}$

Figure 12: Central transverse thrust and central transverse thrust minor compared to CMS data [26].
is largest when $\tau_{\perp, C} (T_{m, C})$ is close to zero (one). The non-perturbative uncertainties have the opposite behaviour.

**Forward energy flow**

The last observable to be studied is the forward energy flow as measured by the CMS collaboration \[27\]. In this analysis, events with at least two jets, defined by the anti-$k_\perp$ algorithm with $R = 0.5$ and $p_\perp > 20$ GeV are required. The two leading jets are further required to lie within $|\eta| < 2.5$ and satisfy $|\Delta \phi - \pi| < 1$, i.e. to produce a nearly back-to-back topology. Within this event sample the energy flow, defined as average energy $E$ per event per pseudo-rapidity interval $d\eta$, is calculated and compared to the measured data. Despite a small difference in shape good agreement is found. Again, due to the normalisation of the observable, renormalisation and factorisation scale uncertainties as well as resummation scale uncertainties are small. A comparably large uncertainty stems from the non-perturbative modelling uncertainties, ranging up to $\sim 10\%$. This is not unexpected since in this very forward region, close to the beams, non-factorizable components of the inclusive cross section play a large role.

**4 Conclusions**

We have presented a detailed analysis of uncertainties associated with the simulation of inclusive jet and dijet production using methods for matching next-to-leading order QCD calculations and parton showers. We have analysed factorisation and renormalisation scale dependence as well as variations originating from the choice of resummation scale. We have compared to uncertainties originating from the freedom in choosing parameters in the Monte-Carlo simulation of multiple parton scattering.

These three types of uncertainties represent different degrees of freedom in the Monte-Carlo simulation: While the renormalisation and factorisation scale dependence probe the impact of higher-order QCD corrections to the hard process, the resummation scale dependence quantifies, to some extent, uncertainties related to parton evolution. Variations of the MPI tune are used to estimate uncertainties related to non-perturbative dynamics.

The results of our Monte-Carlo simulation have been compared to a variety of data taken by the ATLAS and CMS experiments at the CERN LHC. Good agreement is found for almost all observables. Exceptions are the inclusive jet transverse momenta at large jet rapidity and the dijet invariant masses at large average rapidity. Discrepancies are attributed to the choice of renormalisation and factorisation scale, which is given by one quarter of the visible transverse energy. Despite taking into account real-emission dynamics, this scale does not give a realistic measure of the hardness of events at large individual jet rapidities. A modified scale, with jet transverse momenta weighted by their rapidity w.r.t. the centre of the partonic system, leads
to better agreement in the forward region, but deviations are observed for central jet production. Uncertainties related to higher-order corrections to the hard process are most important for exclusive multi-jet final states. Similarly, uncertainties related to the resummation procedure are most significant in the region where jet production is modelled by the parton shower. We expect that both uncertainties can be reduced by application of matrix-element parton-shower merging methods at the next-to-leading order [63–65]. A corresponding analysis is forthcoming. A different role is played by non-perturbative uncertainties. They are most significant in regions where (semi-)soft particle production dominates over multi-jet effects. They can be reduced only by better constraints on the non-perturbative dynamics through additional measurements of underlying event activity and particle flow.

Our analysis should help to better understand the quality of Monte-Carlo predictions, which are obtained using matching methods like MC@NLO and POWHEG. Ascribing reliable uncertainties to such predictions will remain an important task in the immediate future of LHC physics.
