ABSTRACT

Surgically assisted rapid maxillary expansion (SARME) is the treatment of choice to adult patients even with severe transversal maxillary discrepancies. However, the adequate retention period to achieve the bone remodeling, thus assuring treatment stability, is controversial. Objective: To evaluate the opening pattern and bone neoformation process at the midpalatal suture in patients submitted to surgically assisted (SARME) through cone beam computed tomography (CBCT). Material and Methods: Fourteen patients were submitted to SARME through subtotal Le Fort I osteotomy. Both the opening pattern and the mean bone density at midpalatal suture area to evaluate bone formation were assessed pre- and post-operatively (15, 60 and 180 days) through CBCT. Results: Type I opening pattern (from anterior to posterior nasal spine) occurred in 12 subjects while type II opening pattern (from anterior nasal spine to transverse palatine suture) occurred in 2 individuals. The 180-day postoperative mean (PO 180) of bone density value was 49.9% of the preoperative mean (Pre) value. Conclusions: The opening pattern of midpalatal suture is more related to patients’ age (23.9 years in type I and 33.5 years in type II) and surgical technique. It was not possible to observe complete bone formation at midpalatal suture area at the ending of the retention period studied (180 days).

Keywords: Transverse maxillary deficiency. Surgically assisted rapid maxillary expansion. Cone beam computed tomography

INTRODUCTION

Aging results in both bone density increasing and alterations on the biological behavior of the craniofacial complex sutures due to skeletal maturity. Although the increasing of bone rigidity is variable among individuals, it offers greater resistance to the forces applied to midpalatal suture during maxillary expansion1.

Surgically assisted rapid maxillary expansion (SARME) or surgically assisted maxillary expansion (SAME) has been indicated both for patients reaching skeletal maturity and those previously submitted to rapid maxillary expansion (RME) whose treatment failed5,22.

The literature emphasizes the indispensable role of post-expansion orthodontic retention of midpalatal suture14,17,25. Within this retention period, both bone neoformation and suture remodeling takes place, decreasing the relapse possibilities26. In the studies on SARME mentioned in international literature, the mean age of the patients undergoing
SARME varied from 19 to 29. The groups studied were quite small and mostly contained not more than 20 patients. The period of retention after expansion varies from 2 to 12 months. Generally, a period of 3 months is used.

Still, the biological behavior of midpalatal suture of adult patients submitted to SARME has not been fully clarified, especially regarding the time amount required to achieve bone neoformation/mineralization and the adequate retention period to achieve bone remodeling, thus assuring treatment stability.

Cone beam computed tomography (CBCT) is a useful tool to asses quantitatively the effects of maxillary expansion and measure bone density at midpalatal suture area. Moreover, CBCT provides tridimensional visualization of craniofacial structures and other advantages, such as: relatively low cost; no anatomic structure superposition; easy access; and low radiation exposure compared to conventional multislice tomography.

The aim of this study was to evaluate the opening pattern and bone neoformation at the midpalatal suture area, immediately before and during orthodontic retention period, in patients submitted to surgically assisted rapid maxillary expansion through cone beam computed tomography.

MATERIAL AND METHODS

It was a prospective study and the sample comprised 56 digital volumetric tomographies of 14 adult patients (four images per patient), both genders, presenting posterior cross bite due to transversal maxillary deficiency treated by surgically assisted rapid maxillary expansion (SARME), no systemic disease that contraindicated the procedure. The tomography device used in this research was the i-CAT (Imaging Sciences International Hatfield, Pennsylvania, USA). Expanders were intermittently activated. Patients wore either Hyrax (n=8) or Haas (n=6) appliances and did not have any contributory disease contraindicating the surgical procedure. One surgeon performed all surgeries at hospital environment. The images used in this study came from the institutional files. This study was approved by the Ethics in Research Committee protocol number 401.136 and all participants signed an informed consent agreement.

All patients were subjected to modified subtotal Le Fort I with osteotomy of pterygoid pillars and midpalatal suture according to Betts, et al. (1995), but without osteotomy of the nasal septum (Figure 1). The four tomographies were obtained at pre-operative and 15-, 60-, and 180-day post-operative periods for each patient. During the surgery, 1.0 g of cephalothin and 10 mg of intravenous dexamethasone were administered in addition to the drugs needed for the general anesthesia. Cephalothin was maintained for 24 hours and during this period they were under nursing care.

The following activation protocol was used: after a latency period of five days, the screws were turned 0.5 mm per day (¼ turn at the morning and ¼ turn at night) for 7 days followed by no activation for the next 7 days. The activation-latency cycles were interpolated until the palatal cusps of maxillary pre-molars and molars touched the buccal cusps of mandibular pre-molars and molars, achieving the desired expansion.

All tomographies were evaluated through i-CAT Vision software. Firstly irregular tool was used to mark an irregular line from posterior to anterior nasal spine, following the hard palate curvature at sagittal reformations (Figure 2). This tracing enabled to obtain the axial reformation of the marked area and to analyze the opening pattern and bone neoformation density at the midpalatal suture area (Figure 3).

The midpalatal suture opening pattern classification was carried out in all 14 tomographic images at 60-day post-operative period, corresponding to the ending of the expansion period, through visual analysis of the images.

Figure 1- Subtotal Le Fort I osteotomy with zygomatic pillar step
classification was based on the study of Pereira, et al.\textsuperscript{19} (2010), as follows: Type I – opening from anterior to posterior nasal spine; Type II – opening from anterior nasal spine to transversal palatal suture (Figure 4).

To measure the bone neoformation density, HU Statistics tool was used by marking rectangles (1 mm\(^2\)) on all extension of the suture/disjunction of midpalatal suture at about 3 mm spacing among them through Distance tool.

Once the rectangular area was marked, the software provided the mean expressed in Housnfield units (HU). Approximately 15 rectangular marks were performed along with the midpalatal suture on 56 sample images, divided into the following areas: anterior (from the anterior nasal spine to incisor foramen), median (from incisor foramen to transversal palatal suture) and posterior (from...
transversal palatal suture to posterior transversal palatal suture) (Figures 5 and 6).

A single examiner assessed the images. Paired t-test was applied to verify the systematic error, at p<0.05. Dahlberg’s formula was used to evaluate the casual error. ANOVA was applied for statistical analysis. All statistical tests were performed by Statistica 7.0 software.

RESULTS

The studied sample comprised 56 tomographies of 14 individuals (9 females and 5 males) with mean age of 25.3 years (SD=5.71 years). Orthodontic appliances consisted of Hyrax (tooth born) and Haas (tooth and mucosa born), respectively installed in 6 and 8 individuals. Type I opening pattern of midpalatal suture was observed in 12 images, while Type II in 2 images (Figure 7 and 8).

Table 1 displays the bone density mean of the three evaluated maxillary areas: anterior, median and posterior, at each studied period. The bone density at these 3 periods: 15-day post-operative (PO 15), 60-day post-operative (PO 60) and 180-day post-operative (PO 180) was smaller than the Initial Period (Pre) in the three regions studied. The period allowed the evaluation of bone density after that the total activation (PO 60) demonstrated the smallest density values. The density values found after six months retention (PO 180) were lower than the Initial Period (Pre). The last column compares the final and initial density in percentage.

Table 2 shows the density results at each studied period: pre-operative (Pre), 15-day post-operative (PO 15), 60-day post-operative (PO 60), and 180-day post-operative (PO 180) with the mean of each period and the percentage regarding to initial period and analyzed by ANOVA. Statistically significant differences were seen by Tukey test.

Figure 5- Density mean along with the area of interest

Figure 6- Marked anterior, median and posterior areas
Rapid maxillary expansion (RME) is considered to correct even severe transversal maxillary discrepancies. However, RME success rate decreases with aging. Moreover, aging and the increasing of resistance against skeletal expansion is directly related because of cranial and face suture fusion. Accordingly, RME is a treatment with high predictability in children and teenagers, but not in adults, commonly resulting in treatment failure and complications like tooth tipping and reduction in buccal cortical bone thickness.

Ideally, the maxillary orthodontic expansion should preferably occur before 15 years old. However, expansion in individuals reaching skeletal maturity is possible, but without predictable and stable outcomes. RME after the pubertal peak tends to show more relapse, hence it is important to plan expansion (SARME) has been the treatment of choice, well accepted by the literature, to overcome the bone resistance to expansion. This treatment modality consists of associating surgical and orthodontic procedures aiming at providing space on tooth arch for tooth alignment.

A few studies demonstrated through finite element analysis the need of osteotomy of pterygoid pillars to decrease the stress concentration on this area, which was very high when the osteotomy was not performed. Moreover, this procedure prevents damage to sphenoid bone and results in a more uniform expansion of the maxillary posterior area.

Other authors concluded that SARME associated with pterygomaxillary disjunction should be chosen in patients aged above 20 years. The aforementioned study was conducted through computed tomography aiming to compare pre- and post-operative periods of patients submitted to SARME with and without pterygoid pillar disjunction.

SARME is considered a procedure with little risk of serious complications, although major complications are mentioned in literature, such as: life threatening epistaxis to a cerebrovascular accident, skull base fracture with reversible oculomotor nerve pareses and orbital compartment syndrome. Less serious complications reported are post-operative hemorrhage, pain, sinusitis, palatal tissue irritation/ulceration, asymmetrical expansion, nasal septum deviation, periodontal problems and relapse.

The mean age of this study’s patients was 25.3 years (Figure 1 and 2), which is in agreement with

| Patients | Gender | Age | Expander | Opening pattern |
|----------|--------|-----|----------|----------------|
| 1        | F      | 33  | Haas     | Type I         |

* p<0.05

It is worth emphasizing the indispensable role of post-expansion orthodontic retention of the midpalatal suture because at this period both bone neoformation and remodeling take place after disjunction, decreasing relapse possibilities. According to a study which compared the stability between rapid and slow maxillary expansion, the dental arch transverse dimensions showed a more pronounced relapse maintaining approximately 40% of initial molar expansion with significant difference from control. Progel, et al. (1992), Berger, et al.(1998) and Koudstaal, et al. (2005), reported 0.88 mm (12%), 1.01 mm (17.5%) and 0.5 mm (55%) of relapse, respectively, in a 12-month study period. They concluded that expansion obtained with SARPE is stable, but all their patients were still in orthodontic treatment. Although a number of articles on the stability of surgically assisted rapid palatal expansion (SARPE) have been published, the reported stability varies considerably.

After midpalatal suture disjunction, bone repair of the area is required to reach treatment stability. However, literature has reached no consensus regarding to the retention period necessary for bone repair.

The midpalatal suture is the area in which the skeletal expansion is observed after RME or SARME and is commonly seen on conventional occlusal radiographs. On occlusal view, obtained through occlusal radiographs of the maxilla, midpalatal suture is visualized up to the middle of the palate. Consequently, the proper view of the posterior area of palate is not possible because of the superposition of the cranial base structures. Thus, the main advantage of computed tomography (CT) over occlusal radiograph of maxilla is the perfect visualization of the posterior area of midpalatal suture, without interference of the cranial structures.

In one study through CBCT comprising 60 adult and 60 teenager patients, the authors concluded that bone density of adults was significantly higher than that of teenagers, but the density of the anterior palatal area of teenagers was similar to that of posterior palatal area of adults.

Similarly, a CT study with teenagers showed the complete midpalatal suture ossification from anterior to posterior nasal spine after a mean retention period of 8-9 months. Nevertheless, in this present study, the complete bone neoformation...
of midpalatal suture did not take place within the studied period, that is, 180 days (6 months) of retention. These findings were similar to those of the study conducted by Petrick, et al.20 (2011) through CT, who evidenced different density values between pre-operative and 7-month post-operative periods20. The bone density of the anterior, median and posterior areas was 48%, 53% and 75% of their initial values, respectively. The aforementioned study verified that the retention period after SARM should be longer. Probably the difference in the retention periods between these studies occurred because the former employed children submitted to RME20,27. As shown by some studies5,12, RME tends to result in incomplete opening of posterior palatal area and consequently bone repair is faster together with the fact that bone neoformation takes place faster in children27,20.

In this study, similarly to that of Petrick, et al.20 (2011), the density values of the anterior area were significantly smaller than those of median and posterior areas of maxilla. The bone density of anterior, median, and posterior areas was 30.4%, 43.3% and 65.7% of the initial values, respectively.

The authors from this research acknowledge the limitation on the small sample size. A study with a large number of patients, especially older individuals, is needed to conclude emphatically that the age affects the opening pattern and the bone neoformation. Another limitation was the assessment performed by a single examiner.

The importance of this study relies on the fact that the bone density at the ending of the retention period (180 days) was smaller than that before SARME. Accordingly, a retention period longer than 180 days is necessary to find similar density values between pre- and post-operative periods.

CONCLUSIONS

Based on the methodology employed and the results obtained, it can be concluded:

1. The opening pattern of the palatal suture seems to be more related to patients’ age than to type of orthopedic mechanics employed.

2. The bone density values after 180 days of retention were smaller than those of the pre-operative period, demonstrating that this retention period was not sufficient for the complete bone neoformation at the midpalatal suture area of the studied patients.
