ABSTRACT

The origin and evolution of magnetism in OB stars is far from being well understood. With approximately 70 magnetic OB stars known, any new object with unusual characteristics may turn out to be a key piece of the puzzle. We report the detection of an exceptionally strong magnetic field in the He-strong B2IV star CPD $-62^\circ$ 2124. Spectropolarimetric FORS2 and HARPSpol observations were analysed by two independent teams and procedures, concluding on a strong longitudinal magnetic field of approximately 5.2 kG. The quantitative characterisation of the stellar atmosphere yields an effective temperature of 23 650$^{+250}_{-110}$ K, a surface gravity of 3.95$^{+0.10}_{-0.10}$ dex and a surface helion fraction of 0.35$^{+0.05}_{-0.02}$ by number. The metal composition is in agreement with the cosmic abundance standard, except for Mg, Si and S, which are slightly non-solar. The strong and broad (~ 300 km s$^{-1}$) disc-like emission displayed by the H$\alpha$ line suggests a centrifugal magnetosphere supported by the strong magnetic field. Our results imply that CPD $-62^\circ$ 2124 is an early B-type star hosting one of the strongest magnetic fields discovered to date, and one of the most evolved He-strong stars known, with a fractional main-sequence lifetime of approximately 0.6.

Key words. Stars: atmospheres – Stars: evolution – Stars: magnetic field – Stars: massive – Stars: individual: CPD-62 2124

1. Introduction

The recent efforts invested in the search for magnetic fields in the most massive O- and B-type stars have provided more than 70 confirmed magnetic detections (e.g. Petit et al. 2013; Alecian et al. 2014; Fossati et al. 2014; Hubrig et al. 2014a; Neiner et al. 2014; Castro et al. 2015) and a magnetic incidence rate of approximately 7% (Table 1 of Wade et al. 2014; Fossati et al. 2014; Hubrig et al. 2014a). Any new addition to the scarce number of known magnetic stars, especially objects with unusual characteristics, has the potential to improve our understanding of the origin of magnetism and its role in stellar structure and evolution (Langer 2012; Petermann et al. 2013), as well as in the characteristics of the circumstellar environment (Petit et al. 2013) and spectral features linked to the magnetic field (e.g. OP/PP stars; Nazé et al. 2010). Detections of strong (i.e. longitudinal field larger than 1 kG) magnetic fields have been reported in the literature among He-strong stars (e.g. Landstreet & Borra 1978; Borra & Landstreet 1979; Bohlender 1988; Bagnulo et al. 2006; Hubrig et al. 2015), pointing out He-strong stars as a subclass of strong magnetic early B-type stars.

Within the context of the “B fields in OB stars” (BOB) collaboration (Morel et al. 2014, 2015; Hubrig et al. 2014a, 2015; Fossati et al. 2015b; Schöller et al. 2016), here we report the detection of an exceptionally strong magnetic field in the He-strong B2IV star CPD $-62^\circ$ 2124 ($V=11.04$ mag; Drilling 1981; Walborn 1983; Zboril et al. 1997; Renson & Manfroid 2009). The star was observed using two different instruments (Sect. 2) and the magnetic field was detected and confirmed by independent teams employing different techniques (Sect. 3). Section 4 presents the stellar atmospheric and chemical abundance analyses, and gives the derived stellar evolution properties. The results are discussed and conclusions are drawn in Sect. 5.

2. Observations

We observed CPD $-62^\circ$ 2124 on the 17th March, 2015, using the FORS2 low-resolution spectropolarimeter (Appenzeller et al. 1998) attached to the ESO/VLT UT1 (Antu) of the Paranal Observatory (Chile). The data were taken with a slit width of...
0.4" and the grism 600B. This setting led to a resolving power of approximately 1700 and a wavelength coverage from 3250-6215 Å. Eight consecutive exposures of 600 seconds were carried out with a total exposure time of 4800 seconds. More details on the instrument settings and exposure sequence are provided by Hubrig et al. (2014a) (see also Fossati et al. 2015b).

We also observed CPD−62° 2124 with the HARPSpol spectro-polarimeter (Snik et al. 2011; Piskunov et al. 2011) attached to the ESO 3.6m telescope of La Silla Observatory (Chile) on the 4th June, 2015. The HARPSpol data cover the spectral range 3780-6910Å with a resolving power of ≈ 115 000. Four exposures of 1800 seconds each were obtained, rotating the quarter-wave retarder plate by 90° after each exposure (further details are reported by e.g. Hubrig et al. 2014a; Fossati et al. 2015b). The final Stokes I spectrum has a signal-to-noise ratio per pixel of approximately 70, calculated at 5000 Å.

3. The strong surface magnetic field of CPD−62° 2124

The FORS2 data were reduced and analysed using independent pipelines by the Bonn (Fossati et al. 2015b) and Potsdam (Hubrig et al. 2014b) teams. The obtained longitudinal magnetic field values (⟨Bz⟩) are listed in Table 1. Figure A.1 shows the output of the Bonn pipeline, where the strong surface longitudinal magnetic field of CPD−62° 2124 is revealed by the slope in the top-right panel (see Potsdam outcome in Schöller et al. 2016).

Both pipelines led to a strong magnetic field detection using either the hydrogen lines or the whole spectrum. Nonetheless, there is a difference of approximately 600 G between the measurements based on the hydrogen lines, whereas the values are consistent within the errors when the whole spectrum is considered. Such discrepancies for strongly magnetic stars are not uncommon (see Landstreet et al. 2014; Fossati et al. 2015b).

The subsequent HARPSpol spectrum of CPD−62° 2124 confirmed the presence of a strong magnetic field. The HARPSpol data were independently reduced and analysed using different techniques by the Bonn and Potsdam groups, as described in previous BOB works (Hubrig et al. 2014a; Przybilla et al. 2016).

The ⟨Bz⟩ values, derived from the HARPSpol spectra, were estimated adopting two techniques: the least-squares deconvolution technique (LSD; Donati et al. 1997; Kochukhov et al. 2010) and the single value decomposition technique (SVD; Carroll et al. 2012). We derived the ⟨Bz⟩ values considering 90 metal lines and ignoring He lines because of their large width and the inhomogeneous surface distribution that biases the magnetic field measurements (see Table 1). Each analysis of the Stokes V spectra led to a definite detection of the magnetic field, while, as seen in Fig. 1, non-detections were obtained from the diagnostic null profiles (see Baglin et al. 2009 for details).

The LSD analysis of the rather noisy HARPS observations carried out by the Bonn group resulted in a ⟨Bz⟩ value of approximately 5.2 kG. However, the LSD and SVD applied to the spectra reduced by the Potsdam group led to ⟨Bz⟩ values of the order of 3–3.5 kG. On the other hand, if the Potsdam group uses the spectra extracted measurements of the Bonn group, the results obtained for SVD and LSD, 5.1 ± 0.3 kG and 5.4 ± 0.3 kG, respectively, match the Bonn result well. Since the Potsdam analysis is based on two-dimensional spectra extracted using the ESO HARPS pipeline. It is very likely that the pipeline spectrum extraction is sensitive to the noise level in the observed spectra, which in the case of our HARPS observations is rather high compared to our previous observations with this instrument, and

![Fig. 1. LSD profiles of Stokes I, V and N parameters obtained for CPD−62° 2124 by the Bonn group. The vertical dotted lines indicate the velocity range adopted for the determination of the detection probability and (Bz) value. The Stokes V and N profiles have been shifted upwards by an arbitrary value and expanded by a factor of two.](image)

4. Stellar parameters and chemical abundances

CPD−62° 2124 is the second He-strong star for which the BOB consortium discovered the presence of a magnetic field and de-
rived the stellar parameters. Przybilla et al. (2016) presented the magnetic field detection and parameters for CPD −57° 3509, which is also a He-strong B2IV star, though with a weaker magnetic field (B_\parallel = 1.1 \, \text{kG}) compared to that of CPD −62° 2124.

The average projected rotational velocity (v sin i) and macroturbulence (\zeta) velocities of 35 ± 5 km s\(^{-1}\) and 40 ± 5 km s\(^{-1}\), respectively, were obtained from the HARPSpol Stokes I spectrum employing the Iacob-broad code (Simón-Díaz & Herrero 2014). The velocities were independently derived using the tools described by Nieva & Przybilla (2012). The two techniques employed approximately 30 and 90 spectral lines, respectively, belonging to nine different chemical elements (see Table 2). The derived \zeta velocity is approximately 1.5 times higher than the average for stars of similar spectral type (Simon-Díaz et al. 2016). Magnetic splitting could affect the spectral lines, leading to a higher macroturbulence value. Pulsations found in similar B-type stars could also lead to higher macroturbulence (Aerts et al. 2014).

The atmospheric characterisation of CPD −62° 2124 was carried out using the hybrid non-LTE approach described by Nieva & Przybilla (2007) and the same strategy as followed for CPD −57° 3509. A description of the technique, atomic models and limitations is given by Przybilla et al. (2016), with the being that in this analysis we did not consider the hydrogen Balmer lines that are contaminated by circumstellar emission. Exceptions being that in this analysis we did not consider the hydrogen Balmer lines, which show an important contribution from the circumstellar material (Zboril et al. 1997), by fitting the Balmer lines, deriving a higher effective temperature of 26000 K and surface gravity of 4.2 dex. The authors mention the emission in the Balmer lines as a possible source of uncertainty. In addition, their neglect of metal lines and non-LTE effects contributes to the differences.

The lines from the investigated chemical species react differently to magnetic broadening (which is unaccounted for in our modelling). While an overall systematic reduction of abundance values can be expected, the effect should be covered by the 1σ-uncertainties (see Table 2), as implied by the good match of model and observation and the only slightly higher uncertainties with respect to standard B-stars, in the CAS study for example.

The stellar mass (M), radius (R), luminosity (L), evolutionary age (\tau) and fractional main-sequence lifetime (\tau/\tau_{MS}) were derived from comparisons with stellar evolutionary tracks by Ekström et al. (2012) and Brott et al. (2011) (Table 2). When considering the rotating stellar evolutionary tracks by Brott et al. (2011), we inferred stellar parameters using the nonssntool (Schneider et al. 2014). In the relevant mass range, the small differences between the two sets of tracks are attributed mainly to differences in the adopted overshooting parameters (see e.g. Castro et al. 2014). Note that the evolutionary tracks were computed assuming solar abundances, though we expect this to have a small effect because the He overabundance should be confined to the outermost layers only, implying no influence on the evolution of the star (Przybilla et al. 2016).

---

**Table 2. Parameters and elemental abundances of CPD −62° 2124.**

| Parameter          | Value          |
|--------------------|----------------|
| T_\text{eff} [K]   | 23650 ± 250    |
| log g [cgs]        | 3.95 ± 0.10    |
| y [number fraction]| 0.35 ± 0.02    |
| \xi [km s\(^{-1}\)] | 2 ± 1          |
| v sin i [km s\(^{-1}\)] | 35 ± 5        |
| \zeta [km s\(^{-1}\)] | 40 ± 5        |

**Non-LTE metal abundances:**

| Element | CAS | CPD −62° 2124 |
|---------|-----|--------------|
| C       | 3.95 | 3.75         |
| O       | 7.39 | 7.38         |
| Mg      | 6.28 | 6.26         |
| Al      | 6.48 | 6.49         |
| Si      | 7.56 | 7.57         |
| S       | 7.50 | 7.52         |
| Fe      | 7.46 | 7.47         |

**Fundamental parameters:**

| Parameter | Value |
|-----------|-------|
| M/M_\odot | 10.0±0.4 |
| R/R_\odot | 5.8±0.9 |
| log L/L_\odot | 3.98±0.11 |
| \tau [Myr] | 16.4±0.9 |
| \tau/\tau_{MS} | 0.65±0.10 |

**Notes.** The number of lines considered for the determination of the chemical abundances is given in brackets. The cosmic abundance standard (CAS; Nieva & Przybilla 2012) in the solar neighbourhood is given for reference, along with data for Al and S from Przybilla et al. (2013).

---

*Fig. 2. Normalised HARPS spectrum of CPD −62° 2124 (grey solid line) in the Hα spectral region. The synthetic photospheric CPD −62° 2124 spectrum is also shown (black solid line), together with the HARPSpol spectrum of the He-strong stars CPD −57° 3509 (blue line, Przybilla et al. 2016) and that of HD 37479 (red line, e.g. Oksanen et al. 2012). The spectrum of HD 37479 was obtained within the context of the Iacob project (http://vivaldi.ll.iac.es:8080/Iacob/jsp/search.jsp; Simón-Díaz et al. 2011, 2015). The narrow central emission in the CPD −62° 2124 spectrum is of nebular origin.*
5. Discussion and Conclusion

On the basis of the available information, and assuming a dipolar magnetic field geometry, the lower limit on the dipolar magnetic field strength (\(B_1\)) calculated using the relations of [Preston (1967)] and assuming a limb darkening coefficient of 0.3 (see [Claret & Bloemen (2011)]), is equal to 18.3 kG. Note that [Petit et al. (2013)] adopted a more conservative limb darkening coefficient of 0.6, under this approximation \(B_{\text{max}} = 2124\)'s dipolar magnetic field strength is 17.2 kG. Among the known magnetic massive stars, only \(B_{\text{NGC 1624}} = 2.9\) kG [Wade et al. (2012)] and the He-strong star HD 64740 (\(B_1 = 4.8\) kG; [Petit et al. (2013)]) host a magnetic field with a strength comparable to that of \(B_{\text{CD-21 2124}}\).

From the measured \(v \sin i\) value, inferred stellar radius and mass, and assuming an equator-on view, we obtain a maximum rotation period of 7.3 days and an upper limit on the Keplerian corotation radius of 6.7 stellar radii. Adopting \(B_1 = 18.3\) kG, we obtain lower limits on the Alfven radius of approximately 35.2 stellar radii. For these calculations we adopted the stellar parameters obtained from Bonnasa (including a mass-loss rate of \(1.6 \times 10^{-8} M_\odot\,yr^{-1}\)) and a terminal velocity of \(700\,\text{km}\,s^{-1}\) [Oksala et al. (2011)]. Following the results of [Petit et al. (2013)], \(B_{\text{CD-21 2124}}\) should have a centrifugal magnetosphere.

The \(H\alpha\) line profile (Fig. 2) supports the presence of a disc-like centrifugal magnetosphere. The line presents a central absorption component and line-wing emissions on both sides of the \(H\alpha\) line extending up to approximately \(300\,\text{km}\,s^{-1}\). The presence of similar \(H\alpha\) emission wings has been reported for other strongly magnetic He-strong stars, such as HD 23478 \(\langle B_{\text{1245}} \rangle = 1.5\,\text{K}\); [Hubrig et al. (2015)] and HD 37479 \(\langle B_{\text{1245}} \rangle = 2.4\,\text{K}\); [Oksala et al. (2012)], for example. Despite the similarities between the He-strong stars \(B_{\text{CD-21 2124}}\) and \(B_{\text{HD 23478}}\), the latter does not show any spectral feature indicative of circumstellar material (see Fig. 2), although on theoretical grounds it could also host a centrifugal magnetosphere (\(B_{\text{1245}} = 1.1\,\text{K}\); [Przybilla et al. (2016)]). \(B_{\text{CD-21 2124}}\) therefore provides a further empirical constrain on the physical conditions (e.g. stellar evolutionary stage, rotation and magnetic field strength) that need to be met for a magnetic star to host and display the signature of a magnetosphere at optical wavelengths ([ud-Doula & Owocni 2002]; [Shultz et al. (2014)]). The large circumstellar velocities, particularly compared to the low measured \(v \sin i\) value, may be due to the fact that the emission occurs at large stellar radii in conjunction with rigid rotation due to magnetic coupling. In this scenario, the centrifugal magnetosphere peaks at approximately 8.5 stellar radii.

Based on the \(B_1\) value of 18.3 kG and assuming flux conservation as the only mechanism affecting the magnetic field strength, \(B_{\text{CD-21 2124}}\) would have had a dipolar magnetic field strength on the zero-age main-sequence (ZAMS) larger than 34.1 kG (the evolutionary tracks of [Brott et al. 2011] give a ZAMS radius of \(3.7 \,R_\odot\)) [Nieva & Przybilla (2012)]. These values could be even larger, if one accounts for the possibility of magnetic field decay ([Fossati et al. (2016)]) and using the stellar parameters from Bonnasa, a gyration constant of 0.04 (Fossati et al. (2016)) and the mass-loss rate, terminal velocity and maximum rotation period mentioned earlier in this section, we obtain an upper limit on the spin-down age (the time required to spin down a star from critical rotation to the current rotation rate) of approximately 0.8 Myr, which is much smaller than the age of the star, suggesting that the magnetic field might have been generated during the main-sequence evolution, possibly following a merger event.

We derived a chemical composition consistent with the CAS ([Nieva & Przybilla (2012); Przybilla et al. (2013)]) and only silicon, sulphur and magnesium (magnesium abundance based only on Mg in 4481 Å) show small deviations from abundances typical of nearby B stars (off by ≈ 0.25 dex). The large helium abundance \((y = 0.35 \pm 0.02\) number fraction) is the only strong peculiarity derived from the abundance analysis. \(B_{\text{CD-21 2124}}\) adds to the continuously increasing group of He-strong stars for which a magnetic field has been detected. This further supports the hypothesis ([Borra & Landstreet 1979]) that the rise of a surface He overabundance is closely related to the presence of strong surface magnetic fields.

**Fig. A.1.** Overview of the results of the analysis of the FORS2 data of CPD $-62\degree$ 2124 using the Bonn pipeline and considering the hydrogen lines. The top-left panel shows the derivative of Stokes $I$. The regions used for the calculation of the magnetic field are marked by a thick blue line close to the top of the panel. Bottom-left panel: the top profile shows Stokes $I$ arbitrarily normalised to the highest value, the middle red profile shows Stokes $V$ (in %) shifted upwards for visualisation reasons and the bottom blue profile shows the spectrum of the $N$ parameter (in %). The green asterisks mark the points that have been removed by the $\sigma$ clipping algorithm. The pale blue strip superimposed upon the $N$ profile shows the uncertainty associated with each spectral point. The thick green bar on the left side of the spectrum of the $N$ parameter shows the standard deviation of the $N$ profile. The top-right panel shows the linear fit used for the determination of the magnetic field using the Stokes $V$ (i.e. $\langle B_z \rangle$). The red solid line shows the best fit. From the linear fit we obtain $\langle B_z \rangle = 5222 \pm 123$ G. The bottom-right panel is the same as the bottom-left panel, but for the null profile (i.e. $\langle B_z \rangle$). From the linear fit, we obtain $\langle B_z \rangle = 25 \pm 95$ G.
