Constraining stellar evolution theory with asteroseismology of γ Doradus stars using deep learning

Stellar masses, ages, and core-boundary mixing

ABSTRACT

Context. The efficiency of the transport of angular momentum and chemical elements inside intermediate-mass stars lacks proper calibration, thereby introducing uncertainties on a star’s evolutionary pathway. Improvements require better estimation of stellar masses, evolutionary stages, and internal mixing properties.

Aims. Our aim was to develop a neural network approach for asteroseismic modelling, and test its capacity to provide stellar masses, ages, and overshooting parameter for a sample of 37 γ Doradus stars; these parameters were previously determined from their effective temperature, surface gravity, near-core rotation frequency, and buoyancy travel time \( \Pi_b \). Here our goal is to perform the parameter estimation from modelling of individual periods measured for dipole modes with consecutive radial order rather than from \( \Pi_b \). We assess whether fitting these individual mode periods increases the capacity of the parameter estimation.

Methods. We trained neural networks to predict theoretical pulsation periods of high-order gravity modes (\( n \in [15, 91] \)), and to predict the luminosity, effective temperature, and surface gravity for a given mass, age, overshooting parameter, diffusive envelope mixing, metallicity, and near-core rotation frequency. We applied our neural networks for Computing Pulsation Periods and Photospheric Observables (C-3PO) to our sample and compute grids of stellar pulsation models for the estimated parameters.

Results. We present the near-core rotation rates (from the literature) as a function of the inferred stellar age and critical rotation rate. We assessed the rotation rates of the sample near the start of the main sequence assuming rigid rotation. Furthermore, we measured the extent of the core overshoot region and find no correlation with mass, age, or rotation. Finally, for one star in our sample, KIC 12066947, we find indications of mode coupling in the period spacing pattern which we cannot reproduce with mode trapping.

Conclusions. The neural network approach developed in this study allows the derivation of stellar properties dominant for stellar evolution, such as mass, age, and extent of core-boundary mixing. It also opens a path for future estimation of mixing profiles throughout the radiative envelope, with the aim of inferring these profiles for large samples of γ Doradus stars.

Key words. asteroseismology – stars: evolution – stars: oscillations – stars: rotation – stars: interiors

1. Introduction

Accurate predictions of a star’s evolutionary path depend on the accuracy of the description of transport of angular momentum (AM, e.g. Maeder 2009; Aerts et al. 2019) and chemical elements (e.g. Salaris & Cassisi 2017). The transport mechanisms are still poorly understood, thereby introducing uncertainties in state-of-the-art stellar structure and evolution models. These uncertainties already occur during the core-hydrogen burning stage, and hence propagate into models of more evolved stars as well. Asteroseismology, the study of stellar oscillations, in low- to intermediate-mass stars (\( M_\ast \lesssim 3.3 M_\odot \)) constitutes a powerful tool to measure surface and near-core rotation rates across various evolutionary phases: main sequence (MS; Kurtz et al. 2014; Saio et al. 2015; Van Reeth et al. 2016, 2018; Christophe et al. 2018; Ouazzani et al. 2017); subgiants and red giants (Beck et al. 2012; Mosser et al. 2012; Gehan et al. 2018); and white dwarfs (Hermes et al. 2017). The empirically derived rotation rates require the transport of AM to be one to two orders of magnitude more efficient than what is currently predicted by theory (e.g. Cantiello et al. 2014; Fuller et al. 2014, 2019; Eggenberger et al. 2017, 2019a,b; Tayar & Pinsonneault 2018; den Hartogh et al. 2019, 2020). It has been suggested by Eggenberger et al. (2017) that the efficiency of AM transport increases with increasing mass.

Aerts et al. (2019, their Fig. 4) present an overview of measured core rotation rates versus the surface gravity (log \( g \)) in the literature for stars with \( M_\ast \in [0.72, 7.9] M_\odot \). While the different evolutionary stages can be distinguished based on log \( g \), the typical uncertainty is too large to infer any correlations between the rotation rate and the stellar age (Aerts et al. 2017). Instead of using log \( g \) as an age proxy, Ouazzani et al. (2019) used the reduced asymptotic period spacing \( \Pi_b \), which represents the buoyancy travel time throughout the star, as derived for a sample of γ Doradus stars. Such stars are of spectral types from late A to early F (1.4 \( M_\ast \lesssim M_\ast \lesssim 1.9 M_\odot \)) and show gravity (\( g \)) modes excited via a convective flux blocking mechanism (e.g. Guzik et al. 2000; Dupret et al. 2005), although the \( \kappa \) mechanism also plays a role for the hotter members of the class (Xiong et al. 2016).
In a chemically homogeneous non-rotating non-magnetic star, the periods of $g$ modes (with the same spherical degree $\ell$ and azimuthal order $m$, but consecutive radial order $n$) are equally spaced in period in the asymptotic regime ($n \gg \ell$), namely by $\Delta P = P_{n+1} - P_n$ of each individual mode with radial order $n$ is plotted as a function of its period $P_n$. The advent of the Kepler (Borucki et al. 2010) and TESS (Ricker et al. 2015) missions has led to numerous detections of such period spacing patterns in $\gamma$ Dor stars (Kurtz et al. 2014; Saio et al. 2015, 2018; Van Reeth et al. 2015; Keen et al. 2015; Li et al. 2019, 2020; Antoci et al. 2019). A first attempt at estimating stellar masses and ages of a sample of 37 $\gamma$ Dor stars was done by Mombarg et al. (2019) using $\Pi_0$, $T_{eff}$, and $\log g$ assembled in Van Reeth et al. (2015, 2016) as input for the modelling. Their results show that faster rotating stars tend to be in the early phases of the MS, and there was no correlation between age and the detection of Rossby modes. In this paper our aim is to refine their work by fitting the measured periods for each of the individual dipole modes with consecutive radial order instead of just $\Pi_0$ as asteroseismic observable.

In addition to probing stellar rotation rates, asteroseismology also allows the scrutiny of a star’s internal chemical mixing profile (e.g. Pedersen et al. 2018, 2021; Michielsen et al. 2019). During the core-hydrogen burning phase, a chemical gradient is introduced in the near-core region as the mean molecular weight inside the core increases.

The presence of a chemical gradient causes mode trapping, which translates into characteristic dips in the period spacing pattern (Miglio et al. 2008). However, mixing occurs in the core boundary layers, due to effects such as core overshooting and a variety of phenomena occurring at the bottom of the envelope. In addition, mixing throughout the radiative envelope occurs, for example as a result of shear instabilities (Maeder 2009) or internal gravity waves (e.g. Rogers & McElwaine 2017). Such forms of mixing alter the chemical gradient, making it possible to probe the efficiency of the mixing throughout the stellar envelope and infer properties of the mixing profile provided that modes with suitable probing power can be detected and identified (Aerts 2021). This has been achieved for a sample of B-type $g$-mode pulsators, revealing a wide range of mixing levels, from $\sim 10^{-6}$ cm$^2$ s$^{-1}$ (Pedersen et al. 2021). For $\gamma$ Dor stars our understanding of mixing in the envelope is less advanced because their levels of mixing at the deep bottom of the envelope, at the interface with the core overshoot zone, were found to be much lower (Van Reeth et al. 2016; Mombarg et al. 2019).

In this paper we take the first steps towards developing a new modelling approach based on deep learning, with the future aim of estimating the mixing profile throughout the radiative envelope of $\gamma$ Dor stars. In this initial study we only treat the mixing in the near-core boundary layer, while fixing the one in the outer envelope. We do this because we first aim to assess the precision estimation of the global stellar parameters, such as the mass, metallicity, age, and convective core overshooting for an exponential overshooting prescription, by relying on the individual mode period spacings rather than on just $\Pi_0$. In order to test the capacity of our new deep learning method we re-model the measured period spacing patterns of the 37 $\gamma$ Dor stars from the sample of Van Reeth et al. (2015) and derive masses, ages, and near-core mixing efficiencies. These are then compared to those obtained earlier by Mombarg et al. (2019). If we achieve a better modelling strategy based on our initial deep learning approach, then future applications in a much higher-dimensional parameter space become possible, which would allow the additional estimation of the envelope mixing profiles responsible for the observed morphologies of the period spacing patterns in terms of isolated or recurring dips, as observed by Van Reeth et al. (2015), Li et al. (2019, 2020).

2. Deep learning

One of the biggest challenges in asteroseismic modelling of period spacing patterns is that it requires a parameter search in high-dimensional space. The most important parameters are the stellar mass ($M_*$), the initial metallicity $Z$, and the hydrogen mass fraction in the convective core ($X_c$, a proxy for the stellar age). In addition, the chemical mixing profile is typically split in two parts: the convective core overshooting (dark regions in Fig. 1) and the mixing efficiency in the radiative envelope (labelled $D_0$ in Fig. 1). Given that the physical mechanisms at stake are still unknown, both the overshoot and envelope mixing profile are parametrised by a function dependent on the local radius $r$, where the exact functional description in real stars is still a matter of debate (e.g. Aerts 2021, for a general discussion and example profiles). Mombarg et al. (2019) showed that diffusive exponentially decaying core overshooting cannot be distinguished from convective penetration in their modelling based on $\Pi_0$. As our main aim here is to evaluate our new deep learning modelling method (in terms of its capacity to estimate the global parameters) and not to investigate the detailed morphology of the period spacing patterns, we rely on an exponentially decaying diffusive core overshooting prescription. Our focus thus lies on the parameter estimation delivered by the individual period spacing values coupled to a neural network. The diffusive overshooting is expressed as a dimensionless parameter $f_{os}$ times the pressure scale height (Freytag et al. 1996)

$$D_{CBM}(r) = D_{CBM}(r_0) \exp \left( -\frac{2(r - r_0)}{f_{os}H_H(r_{cc})} \right),$$

(1)

where $r_{cc}$ and $H_H$ are the distance from the stellar centre to the (Schwarzschild) core boundary and pressure scale height, respectively. For numerical purposes the mixing efficiency at the stitching point between convective mixing in the core and the core overshoot mixing is evaluated at $r_{cc} = f_{os}H_H(r_{cc})$, for which we set $f_0 = 0.005$. As said, we do not focus on the shape of the mixing profile in the outer radiative envelope in this first application of the neural network. Hence, we assume a constant mixing efficiency throughout the radiative zone for simplicity.

Aside from these most important parameters for determining the stellar structure and evolution (SSE) models, $M_*$, $Z$, $X_c$, and $f_{os}$, we introduce the internal rotation frequency $f_{rot}$ at the level of the pulsation computations. Hence, asteroseismic modelling of stars with a convective core is in general a +6D problem (Aerts et al. 2018; Aerts 2021). This modelling scheme rapidly becomes computationally expensive with the option to also assess mixing profiles via free parameters and for application to large $\gamma$ Dor sample sizes such as the one provided by Li et al. (2020). To deal with such types of future applications, grids of stellar or pulsation models can be approximated and replaced by statistical models (Mombarg et al. 2019; Pedersen et al. 2021) or neural networks (this work). The latter method has been applied to non-rotating pulsation models for a benchmark sample of pulsating B-type stars by Hendriks & Aerts (2019), reaching an accuracy of $\sim 10\%$ on the pulsation frequencies predicted by deep learning models, compared to those from the pulsation models. The observed values for $Z$ and $f_{rot}$ show that the stars
Fig. 1. Chemical mixing profile showing the different mixing zones in a model for an intermediate-mass star. The ordinate shows the local efficiency of chemical (diffusive) mixing. The thin outer convection zone is not shown in the plot. The radii of the convective core boundary \( r_{cc} \) and overshoot zone \( r_{ov} \) are also indicated. Mixing inside the convective regions is based on MLT and occurs instantaneously. The red dashed line slightly to the left of \( r_{cc}/R_\star \) indicates the starting point of the overshoot zone \( r_{ov} \) in Eq. (1)).

in our sample cover a large range. Furthermore, the \( \gamma \) Dor instability strip is narrow compared to those of other pulsators. As such, properly covering the most important stellar parameters with an equally spaced linear grid set-up, as is commonly done in asteroseismic modelling, would require a very large number of equilibrium models. We want to circumvent this by replacing the application of deep learning to asteroseismic modelling, with an equally spaced linear grid set-up, as is commonly done in asteroseismic modelling, with a neural network (NN). This study serves as an initial proof-of-concept study of the application of deep learning to asteroseismic modelling of \( g \)-mode pulsators, with the idea that future studies may rely on a larger set of grids with different input physics.

2.1. Predicting pulsation periods

For this work we trained a NN to predict \( g \)-mode periods of theoretical pulsation models for given values of \( M_\star \), \( X_\star \), \( Z \), \( f_{ov} \), \( D_0 \), and \( f_{fo} \). We chose this approach instead of using the asteroseismic data as input and the stellar parameters as output (e.g. Hon et al. 2020) because it allows more flexibility in the number of free parameters, as we can fix some of these parameters without having to retrain the NN. We kept this outlook in mind for future applications based on more complex envelope mixing profiles. In this initial study we computed a grid of stellar equilibrium models for the parameter ranges listed in Table 1 based on the ranges used in Mombarg et al. (2019). We based our range of \( f_{ov} \) on the typical values found by Claret & Torres (2017) for the appropriate mass regime. The parameter space was sampled linearly and quasi-randomly from a Sobol sequence, following Bellinger et al. (2016). This way we obtained a high sampling density for each parameter, whilst also allowing the parameters to vary independently. The stellar equilibrium models were computed with the SSE code MESA (r1701) (Paxton et al. 2011, 2013, 2015, 2018, 2019) for the computations of the stellar equilibrium models, using the same input physics as the models without atomic diffusion described in Mombarg et al. (2020). The stars in our sample are assumed to have a chemical mixture similar to the Sun, that is, we take the solar abundances from Asplund et al. (2009), and scale them according to the metallicity \( Z \). The helium mass fraction of the models are set according to the enrichment rate found by Verma et al. (2019) and the initial hydrogen mass fraction is set by \( X_{\text{ini}} = 1 - Y_{\text{ini}} - Z = 0.756 - 2.226Z \) with the \(^{2}\text{H}/^{1}\text{H} \) and \(^{3}\text{He}/^{4}\text{He} \) isotope ratios set to the values measured by Asplund et al. (2009).

From the stellar equilibrium models, the theoretically predicted pulsations are computed with the pulsation code GYRE (v5.2; Townsend & Teitler 2013; Townsend et al. 2018), using the adiabatic framework and treating the Coriolis acceleration non-perturbatively. The equations of motion are decoupled in the angular and radial components by neglecting the latitudinal component of the rotation vector (traditional approximation of rotation, TAR; Eckart 1960; Townsend 2003). Analyses of large samples of \( \gamma \) Dor stars by Van Reeth et al. (2016) and Li et al. (2020) reveal that the prograde dipole mode \((\ell, m) = (1, 1)\) is by far the most observed mode geometry. Hence, for each stellar equilibrium model we computed the predicted pulsation frequencies for \((\ell, m) = (1, 1)\) modes and radial orders \( n \in [15, 91]\) (thus \( \Delta P_n \) for \( n \in [15, 90]\), using the pulsation code GYRE (Townsend 2003; Townsend & Teitler 2013). The range of radial orders is based on the distribution found by Li et al. (2020), taking the most ubiquitous ones. Again, we quasi-randomly sampled \( X_\star \) and \( f_{fo} \) within the ranges listed in Table 1. The rotation frequency range is based on the minimum and maximum observed values in the sample of Van Reeth et al. (2016). The total output data set contains 38915 pulsation models, of which 70% are used for training and 30% for validation.

Neural networks are powerful numerical methods suitable for treating multi-dimensional and complex regression problems (see Bishop 1995; Glorot et al. 2011, for an introduction and general overview on deep learning). We constructed a dense NN comprising five layers, using the KERAS package for Python (with Tensorflow 1.14.0, for which we found that the ReLU activation functions yielded the best performance for our NN. The output of the NN are the predicted periods of radial orders \( n \in [15, 91]\). Similarly constructing statistical models as a means to represent reality, adding non-linear combinations of the input parameters can increase the performance of a NN. Inspired by the regressions performed in Mombarg et al. (2019), we found the performance of our NN to be enhanced by adding two product terms of the most correlated parameters, the mass and age, and mass and metallicity, to the input vector \( \theta = (M_\star, X_\star, Z, f_{ov}, D_0, f_{fo}, M_\star \cdot X_\star, M_\star \cdot Z) \). Each component of \( \theta \) is normalised as

\[
\tilde{\theta}^i_j = \frac{\theta^i_j - \min \theta^i}{\max \theta^i - \min \theta^i},
\]
where \(i\) is the parameter index and \(j\) the model index. The technique of ‘early stopping’ is applied to prevent the loss from increasing again after several epochs; that is, the training is terminated when the validation loss has not decreased during three consecutive epochs. The weights are then restored to the configuration for which the validation loss was the lowest.

The problem of overfitting is common when training a NN; that is, the NN achieves a high precision on the training set while it fails to generalise the correlations, and thus underperforms on their predictions; this technique is often referred to as ensemble learning.

As a function of epoch. In the top panel of Fig. 3 we show the learning curves for all NNs trained to predict the pulsation periods of \((l, m) = (1, 1)\) modes for a given \(\theta = (M_\star, X_\star, Z, f_{\text{rot}}, D_0, f_{\text{rot}}, M_\star, f_{\text{rot}}, M_\star, Z)\). The values of the input parameters are transformed following Eq. (2).

### 2.2. Lifting degeneracies

The modelling of mode periods or period spacing patterns is prone the degeneracies, mainly between mass and age, and mass and metallicity (e.g. Moravveji et al. 2015; Mombarg et al. 2019, 2020). We apply the same methodology as Mombarg et al. (2020), where the best model is selected from models that are compatible with the effective temperature \((T_{\text{eff}})\) and surface gravity \((\log g)\), measured from spectroscopy. In addition to these two parameters, the luminosity \((\log (L/L_\odot))\) derived from the Gaia DR2 distances \((D)\) measured by Bailer-Jones et al. (2018) is used:

\[
\log L/L_\odot = -0.4 (M_\star - V_\odot - 31.572 + [BC_V - BC_{V_\odot}]).
\]

Here \(M_V = m_V - 5 \log(D/10\text{ pc}) - 3.3E(B-V), \ V_\odot = -26.76, \) and \(BC_{V_\odot} = -0.080.\) Bolometric corrections (BC\(_V\)) are computed following Torres (2010), and reddening corrections \(E(B-V)\) are taken from the Bayerstar\(_{2019}\) extinction map (Green et al. 2018). From the extinction, the correction to the visual magnitude is calculated using \(A_V = 3.3E(B-V)\). Figure 4 shows the position of all stars in our sample in a Hertzsprung-Russell diagram (see Table A.1).

In addition to the mode periods, we trained two NNs to predict \((T_{\text{eff}}, \log g)\) and \(\log L\) using the same configuration as the network shown in Fig. 2. To train these NNs, we use all the time steps (on the MS) computed by MESA as opposed to using only the time step for which pulsation models were computed, which means that the training set comprises 423591 vectors and the validation set comprises 141231 vectors. In Fig. 5 we compare the predictions of the NNs of these photospheric observables to MESA evolutionary tracks. We obtain mean absolute errors of \(\bar{e}_{\log L/L_\odot} = 0.010, \bar{e}_{\log T_{\text{eff}}} = 0.004, \) and \(\bar{e}_{\log g} = 0.011\) dex on the uncertainties on the measured periods from Kepler light curves (e.g. Buysschaert et al. 2018; Mombarg et al. 2020).
3. Asteroseismic modelling

Until recently, g-mode modelling of single γ Dor stars relied on \((\Pi_0, T_{\text{eff}}, \log g)\) as input (Mombarg et al. 2019). In the work by Mombarg et al. (2020), \(\Pi_0\) is replaced with the individual mode periods as asteroseismic input for the modelling of two slowly rotating γ Dor stars. Furthermore, these authors investigated whether \(T_{\text{eff}}\) and \(\log g\) should be added to the fit or used as a posteriori to select models that are consistent within \(\sigma r\) compared to the observations. As typically tens of excited modes of consecutive radial order are observed in a single star, the spectroscopic observables have little relative weight in the merit function. Therefore, we opted to use the \(\log T_{\text{eff}}\) and \(\log g\) to select the best-fitting model from a subset of models which are within the \(2\sigma r\) uncertainty ranges of these photometric observables. Aerts et al. (2018) introduced the Mahalanobis distance (MD) as a merit function in asteroseismic modelling to account for the correlated nature of the observed periods and for the theoretical uncertainty of the modes. The MD takes the (co)variances of the input parameters into account such that the contours of equal MD are aligned with the principal components, whereas for the \(\chi^2\) merit function contours of equal \(\chi^2\) are aligned with the base vectors (free parameters). For a given vector \(\mathbf{y}^{(\text{obs})}\) containing the periods of the identified radial orders, and a vector \(\mathbf{y}^{(\text{th})}\) containing the observed periods, the MD is defined as

\[
\text{MD} = (\mathbf{y}^{(\text{th})} - \mathbf{y}^{(\text{obs})})^\top (\mathbf{V} + \mathbf{\Sigma})^{-1} (\mathbf{y}^{(\text{th})} - \mathbf{y}^{(\text{obs})}).
\]

The matrix \(\mathbf{V}\) is the (co)variance matrix and \(\mathbf{\Sigma}\) is a diagonal matrix, constructed from the uncertainties on the predicted mode periods by the NN. These can be treated as aleatoric, as the residuals on the training and validation set follow a normal distribution (see Appendix C). Therefore, each uncertainty \(\sigma_{\mathbf{p}^{(\text{obs})}}\), with \(n\) the radial order, is taken to be the standard deviation of the residuals over the complete grid of pulsation models. The uncertainties of the predictions are typically two orders of magnitude larger than those from the observations.

The matching between the observed radial orders to those from a model is non-trivial. Observed period spacing patterns of γ Dor stars do not always form a single sequence of consecutive radial orders, but may be interrupted by missing modes. Therefore, the radial order matching in this paper is performed as follows:

1. Start with the longest observed continuous sequence of \(M\) periods and assign the shortest period \(P_0^{(\text{obs})}\) to the best-matching period \(P_0^{(\text{th})}\) as the shortest period has the smallest relative uncertainty;
2. Assign periods \(P_1^{(\text{obs})}, \ldots, P_M^{(\text{obs})}\) to the consecutive radial orders in the model;
3. Repeat step 1 for the second longest sequence, and so on. When a radial order is selected that has already been assigned to an observed period in one of the longer sequences, omit the model.

In this way we account for the possibility of having multiple sequences of consecutive radial orders with missing modes.
Table 2. Summary of the network configuration of C-3PO.

| Output | Configuration | Networks |
|--------|---------------|----------|
| $P_n, n \in [15, 91]$ | 700, 700, 20 000, 20 000, 86 | 6 |
| log $L/L_\odot$ | 700, 700, 20 000, 20 000 | 1 |
| log $T_{\text{eff}}, \log g$ | 700, 700, 20 000, 20 000 | 2 |

Notes. The second column lists the number of neurons for each layer.

between these sequences. The construction of $V$ can be done in two ways. In method 1, for each evaluated model $j$, each of the observed periods $P_j^{(\text{obs})}$ is matched with a period $P_j^{(\text{th})}$ corresponding to a radial order that may vary for different models. Matrix $V$ is given by

$$V = \frac{1}{q-1} \sum_j \left( Y_j^{(\text{th})} - \bar{Y}_j^{(\text{th})} \right) \left( Y_j^{(\text{th})} - \bar{Y}_j^{(\text{th})} \right)^T,$$

where $q$ is the number of evaluated models, and

$$Y_j^{(\text{th})} = \frac{1}{q} \sum_j Y_j^{(\text{th})}.$$

In method 2 we take $Y_j^{(\text{th})}$ to contain the periods of all the radial orders predicted by the NN, that is, $n \in [15, 91]$, and construct $V$, thereby yielding a matrix with dimensions $77 \times 77$. Consequently, for each model with radial order identifications $n_{\text{min}}, \ldots, n_{\text{max}}$ corresponding to the $N$ observed mode periods, we remove the rows and columns of $V$ belonging to the radial orders that were not identified in model $j$, yielding an $N \times N$ matrix, $V_j'$.

In the present paper, we used method 2 to compute the MD, such that the (co)variances do not depend on the radial order identification. This is the case for method 1 because the lowest period is matched first and the consecutive periods are then matched to the consecutive radial orders of the model. Hence, when the observed $P_0$ does not match the $P_0$ of the model, the discrepancy between the model and observations is larger for higher radial orders. Therefore, the variance across the grid will also be larger for these radial orders, and by extension will be given a smaller weight. The maximum likelihood estimate (MLE) for our method is not equivalent to minimising the merit function, as is the case for $\chi^2$. Instead, the likelihood of the observed data $D$, given parameters $\theta = (\theta^1, \theta^2, \theta^3)$, is given by

$$L(\theta|D) = P(D|\theta)$$

$$= \exp \left( -\frac{1}{2} \left[ \ln |V'| + MD + k \ln(2\pi) \right] \right),$$

where $k = 3$ is the number of free parameters. According to Bayes’ theorem, the probability of component $\theta^i$ being within interval $[\theta^i_{\text{min}}, \theta^i_{\text{max}}]$ is given by

$$P(\theta^i_{\text{min}} < \theta^i < \theta^i_{\text{max}}|D) = \frac{\sum_i P(D|\theta^i)P(\theta^i_{\text{min}})P(\theta^i_{\text{max}})}{\sum_i P(D|\theta^i)P(\theta^i)},$$

The sum over index $i$ is taken over the $g$ models with the highest likelihood such that $P(\theta^i_{\text{min}} < \theta^i < \theta^i_{\text{max}}|D) = 0.68$, where the sum over index $j$ is taken over all of the models that are consistent with the observed photospheric observables.

The modelling of $g$ modes in $\gamma$ Dor stars is a high-dimensional, degenerate problem. Optimising all six parameters at once will lead to noisy solution spaces, making uncertainty determination unwieldly. However, some parameters are more dominant than others, and thus we first focus on the parameters that have the largest influence on the mode periods. Since the metallicity and near-core rotation rate have already been determined by Van Reeth et al. (2016), we fix these two parameters to the measured values. The influence of $f_{\text{ov}}$ and specifically $D_0$, on the period spacings are mostly seen in the mode trapping. In this work our aim is not to precisely model the trapped modes, but rather get an accurate fit to the global pattern of all observed modes. Accurately modelling trapped modes adds additional dimensionality to the problem in the form of structured (non-constant) mixing profiles (Pedersen et al., 2021), which we do not consider here. For each star in our sample a best-fitting model is found as follows:

1. Randomly sample 5000 models in $(M_*, X_c, f_{\text{ov}})$ with C-3PO, where $Z$ and $f_{\text{ov}}$ are fixed to the measured values, and $D_0 = 1 \text{ cm}^2 \text{s}^{-1}$;  
2. If some observed periods cannot be matched in 90% of the models (because the radial order is outside the range of NN) remove either the shortest or the longest period depending on which one is outside the range. Repeat until a model can be matched;
3. From these 5000 models get the minimum and maximum values of $M_\star$ and $X_\star$ such that the predicted $\log (L/L_\odot), \log T_{\text{eff}}$, and $\log g$ are consistent within $2\sigma$ of the respective uncertainties.

4. Randomly sample 15 000 models, but now within the mass and $X_\star$ ranges obtained in the previous step. The solution and uncertainties are computed according to Eqs. (7) and (8).

5. Since the exact periods of trapped modes are difficult for a NN to predict, we optimise the overshoot parameter with GYRE models once we have a good estimate of $(M_\star, X_\star, f_{\text{rot}})$ from the previous steps. We compute GYRE models for $f_{\text{rot}}\in [0.005, 0.010, 0.015, 0.020, 0.025, 0.030, 0.035]$ for the MLEs for $M_\star$ and $X_\star$ and for the upper and lower limits of these two parameters (63 models per star in total). Models rotating faster than the critical Roche frequency, $\Omega_{\text{crit, Roche}} = (8GM_\star/(27R_\star^3))^{1/2}$, are not taken into account.

In the last step a $\chi^2$ merit function is used instead of the MD as scanning such a small parameter range results in (co)variance uncertainties:

$$
\chi^2_{\text{fit}} = \chi^2_{\text{min}} \left( 1 + \frac{2}{N - k} \right). 
$$

For stars where an additional mode geometry has been observed, the corresponding pulsation models are also computed and fitted simultaneously with the prograde dipole modes in Step 5.

3.1. Theoretical benchmark

First, we demonstrate the capabilities of C-3PO by applying the NN to a set of benchmark models (1.35 $M_\odot$, 1.65 $M_\odot$, 1.95 $M_\odot$) which were not included in the training and validation set. We use radial orders $n \in [20, 60]$, and the photospheric observables from the MESA model as input, where we assume the following uncertainties: $\sigma_{\log L/L_\odot} = 0.05$ dex, $\sigma_{\log T_{\text{eff}}} = 0.015$ dex, and $\sigma_{\log g} = 0.6$ dex. The metallicity and rotation frequency are fixed to the values of the models in the fit since these are also known for the observations. Two examples are shown in Fig. 6, for a young star and an old star. The accuracy of the NN is lower for patterns with clear mode trapping, yet in both cases the periods are still predicted with enough accuracy such that, with the inclusion of the photospheric observables, $M_\star$ and $X_\star$ can be recovered. In Fig. 7, we show the mass and $X_\star$ values of all the inputs models, and the obtained estimates from C-3PO. On average the input mass, $X_\star$, and $f_{\text{rot}}$ are recovered within 2%, 15%, and 16%, respectively. It should also be noted that, as mentioned before, degeneracies exist between young lower-mass stars and old higher-mass stars. Thus, even if the NN were able to perfectly predict the pulsation periods, exactly recovering a (perturbed) input model would still be impossible (see middle panels of Fig. 6).

3.2. Observational benchmark

One of the stars in our sample, KIC 9751996, has been analysed by Mombarg et al. (2020) who modelled the star using models both with and without atomic diffusion (including radiative levitation). As mentioned before, in this paper we use the same input physics in our models compared to their grid without atomic diffusion. It should be noted, however, that in this work only the periods of the prograde mode are modelled, whereas in Mombarg et al. (2020) the periods of the retrograde, zonal, and prograde are modelled simultaneously. This yields $M_\star = 1.740^{+0.009}_{-0.012} M_\odot$, $X_\star = 0.241^{+0.147}_{-0.169}$, and $f_{\text{rot}} = 0.0124^{+0.0121}_{-0.0024}$, which are consistent with the values found by Mombarg et al. (2020). The predicted period spacing pattern of this best-fitting model from C-3PO is shown in Fig. 8.

4. Application to the sample

For all 37 stars in our sample, we apply the modelling scheme discussed in Sect. 3 to constrain $M_\star, X_\star$, and $f_{\text{rot}}$ in order to compare the results with those based on P0 obtained by Mombarg et al. (2019). We recall that our aim is not to achieve good fits to the dips in the patterns, as this requires stratified envelope mixing profiles (Pedersen et al. 2021). Here we merely wish to compare the capacity of the NN with previous modelling based on actual equilibrium models rather than a numerical NN approximation thereof.

Figure 9 shows the mass and $X_\star$ of the best model predicted by C-3PO for each star. As is expected from the position of the $\gamma$ Dor instability strip (Dupret et al. 2004), there is a correlation between the estimated mass and age (i.e. no young more massive or old less massive stars are observed), as already found by Mombarg et al. (2019). KIC 2710594, KIC 3448365, KIC 6678174, KIC 6953103, KIC 7380501, KIC 8645874, KIC 11099031, and KIC 11294808 are stars for which a particularly complicated period spacing pattern is observed (i.e. large deviations in the observed morphology occur compared to what we expect from the pulsation models limited to the physics described in this work). For these stars, part of the pattern has not been taken into account in the fitting. In the cases of KIC 5522154, KIC 5708550, KIC 6678174, KIC 6953103, and KIC 7365537, the best solutions to the observed mode periods do not seem to be in agreement with the photospheric observables. The former and latter are fast rotators ($f_{\text{rot}} > 2.15$ d$^{-1}$; Van Reeth et al. 2016), and hence the inferred $T_{\text{eff}}$ could suffer a larger systemic error due to the larger uncertainty of the spectrum normalisation and gravity darkening. For the other three stars, it is primarily the luminosity that does not agree with the observed pulsations. For these five stars no $2\sigma$ cutoff in $L, T_{\text{eff}}$, and $\log g$ is imposed, resulting in a larger uncertainty on $M_\star$ and $X_\star$, as can be seen in Fig. 9.

We have investigated the effect of adding the rotation frequency (within the observational uncertainties) as an additional free parameter in the fitting on the MLEs. For both the fastest rotating star (KIC 12066947) and the star with the least precisely determined rotation rate (KIC 6678174), fixing the rotation rate in the modelling yields consistent estimates of the varied stellar parameters, compared to when we allow it to vary.

In addition to the $(\ell, m) = (1, 1)$ modes, Van Reeth et al. (2016) also observed $(\ell, m) = (1, 0)$ modes for KIC 4846809 and KIC 9595743 and an $(\ell, m) = (2, 2)$ mode for KIC 11294808. The additional period spacing patterns of these three stars are also taken into account in Step 5 of the modelling scheme (Sect. 3).

Table 3 lists the parameters of the best models found by C-3PO and of the best-fitting GYRE model. In Appendix D we show the theoretically predicted period spacing patterns for all stars in our sample, as well as the distribution of radial orders, similar to the result from Li et al. (2020). Moreover, the Brunt–Väisälä frequency profiles of the best-fitting models are shown in Fig. D.39. In many cases we are not able to reproduce the wiggly characteristics of the observed patterns, indicating that
Fig. 6. Examples of the recovered mass and \( X_c \) of two benchmark models (white stars: input; red stars: best model predicted by NN). Although the period spacings of trapped modes are more difficult to predict (bottom panel), the inclusion of the photospheric observables yields accurate predictions of the mass and \( X_c \). Middle panels: sampling density is increased in the parameter space where the predicted photospheric observables comply with those of the input model (see Sect. 3). Model 1: \((M_\star, X_c, Z, f_{\text{ov}}, D_0, f_{\text{rot}}) = (1.35 M_\odot, 0.515, 0.014, 0.0225, 1 \text{ cm}^2 \text{s}^{-1}, 0.7457 \text{ d}^{-1})\). Model 2: \((M_\star, X_c, Z, f_{\text{ov}}, D_0, f_{\text{rot}}) = (1.95 M_\odot, 0.8, 0.014, 0.0225, 1 \text{ cm}^2 \text{s}^{-1}, 0.0449 \text{ d}^{-1})\). Typical uncertainties on \( \Delta P \) are of the order of several tens of seconds.

The physics used in this work is still incomplete and requires improvement. Therefore, these deviations between the patterns from our best solution and those found in the observations offer a fruitful guide to future studies with the aim of explaining the morphology of the patterns, by means of different core-boundary mixing prescriptions and/or introducing stratified envelope mixing profiles. In order to guide these future studies, we focus on one of the stars in our sample (KIC 11294808) which shows clear ‘wiggles’ in its observed period spacing patterns. With the overshoot prescription used in this work (Eq. (1)), such wiggles are only observed in our models at a level of \( D_0 = 0.05 \text{ cm}^2 \text{s}^{-1} \) (see Fig. E.1). The same conclusion is found for this star when we recompute the MESA and GYRE models, but this time using a step-like penetrative convection prescription as convective-boundary mixing prescription, where we explore \( \alpha_{\text{ov}} \in [0.05, 0.35; 0.05] \) (other parameter ranges kept the same). We obtain the same best model as for an exponential core overshoot in terms of mass and evolutionary stage. This corresponding best convective

Moravveji et al. (2016). This solution is also shown in Fig. 10 the way to include these types of phenomena by modelling the tooth like features (e.g. Prat et al. 2019; Van Beeck et al. 2020); Pedersen et al. (2021), this causes structure to occur in the pat- terns. The structure can have various physical causes, for exam- ple atomic diffusion with radiative levitation (e.g. Deal et al. 2019). This suggests that the correlation between overshooting and the mass was found by these authors from isochrone fitting of binary systems, plateauing to a constant value that is needed to have the correct core properties (their model M01) is also shown (blue dots). For comparison, the solution from Mombarg et al. (2020) without atomic diffusion (their model M01) is also shown (black dots, prograde dipole mode only) and the best-fitting pattern predicted with C-3PO (red dots). For comparison, the solution from Mombarg et al. (2020) without atomic diffusion (their model M01) is also shown (blue dots). The observational uncertainties are typically smaller than the symbol size.

penetration model has a value of $\alpha_{ov}$ that is ten times the value of $f_{ov}$, in agreement with previous studies where such comparisons were made (Moravveji et al. 2016). This solution is also shown in Fig. D.30 (grey open circles).

The remaining differences between the observed and predicted mode periods via the NN seen in most of the stars is due to the lack of stratified envelope mixing. As shown by Pedersen et al. (2021), this causes structure to occur in the patterns. The structure can have various physical causes, for example atomic diffusion with radiative levitation (e.g. Deal et al. 2020; Mombarg et al. 2020); magnetism, which causes saw-tooth like features (e.g. Prat et al. 2019; Van Beeck et al. 2020); shear instabilities due to rotation or wave mixing (Pedersen et al. 2021); or non-linear effects (discussed below). Our results open the way to include these types of phenomena by modelling the residuals between the periods predicted by the current initial NN and the observed ones.

As an extra sanity check to assess the quality of the NN solution, we show in Fig. 10 the $\Pi_0$ value derived from our best model and compare it to the observational values from Van Reeth et al. (2016, 2018) as derived from the mode identification along with the near-core rotation frequency. In general, we find adequate correspondence between the two ways of estimating $\Pi_0$. The most significant discrepancy is found in KIC11099031 (data point indicated in red). This is one of stars for which Christophe et al. (2018) found a much lower value of $\Pi_0$, compared to Van Reeth et al. (2016) (see Fig. 5 in Ouazzani et al. 2019).

4.1. The possible origins of CBM

The parameters of the best-fitting models discussed in this section are those extracted from the MESA and GYRE models computed in Step 5 of the modelling scheme. As illustrated in Fig. 11, the modelling of individual pulsations instead of the method employed by Mombarg et al. (2019) provides a better constraint on $f_{ov}$ as the individual mode periods lead to less degeneracy with respect to the stellar mass and age. In addition, the luminosity is in general more precisely determined than $\log g$ for F-type stars, which further reduces the degeneracy between the stellar mass and age. The overshoot parameter has been asteroseismically calibrated for eight solar-like oscillators with a convective core by Deheuvels et al. (2016), covering a mass range from roughly 1.1 to 1.45 $M_\odot$. They observe an increase in the overshoot parameter with increasing mass, although this trend is much less pronounced for $M_4 > 1.25 M_\odot$. The results from Deheuvels et al. (2016) for models with microscopic diffu- sion are shown in Fig. 11 (in grey). To convert from a step-like overshoot (penetrative, $\alpha_{ov}$) to the exponential overshoot (dif- fuse) parametrization used in this work, we use the approximation $\alpha_{ov} \approx 10f_{ov}$ inferred by Claret & Torres (2017). A similar correlation between overshooting and the mass was found by these authors from isochrone fitting of binary systems, plateauing to a value of $\sim 0.0175$ for $M_4 \gtrsim 2.0 M_\odot$.

For the single stars modelled in this work, however, we do not observe such a mass—overshoot relation, even though a much smaller range in mass is probed. Furthermore, for a significant portion of the sample, we obtain higher values for $f_{ov}$ than those from Claret & Torres (2017). Caution is advised when compar- ing overshoot values between different studies; the exact location in the star where the overshoot (core boundary mixing; CBM) profile starts is set by an additional parameter, $g_0$, normalised by the local pressure scale height, for which we use 0.005 in this work. In Fig. 12, the extent of the overshoot zone is plotted against $X_c/X_{ini}$. The size of the overshoot region is defined as the difference between $r_{ov}$ and $r_{cc}$, where $r_{cc}$ is defined as the radius where the temperature gradient transitions from adia- batic to radiative, and $r_{ov}$ is the radius where the overshoot zone ends (cf. Fig. 1). No evident correlation is observed between the extent of the overshoot zone and the evolutionary stage, although the most evolved stars in our sample typically have smaller over- shoot zones. It should be noted that if the value of $f_{ov}$ is depen- dent on the stellar age, this is not taken into account in the current SSE models. The modelling of period spacing patterns does not probe the value of $f_{ov}$ at the current age of the star, but rather the constant value that is needed to have the correct core properties at the age when the observations were taken. As illustrated in Fig. 13, we observe a correlation between the core mass ($m_{cc}$) and the extent of the overshoot region. An increase in $r_{ov} - r_{cc}$ with increasing $m_{cc}$ is observed where there is an offset between younger and older stars. For the less massive stars, the convective core grows in mass at first, whilst for the more massive stars, the core recedes throughout the MS (see Fig. 2 in Mombarg et al. 2019). This suggests that the correlation between $r_{ov} - r_{cc}$ and $m_{cc}$ is dependent on the core density. The fractional core mass versus the stellar mass is shown in Fig. 14.
Although we refer to \( f_{ov} \) as the convective core overshoot parameter, \( f_{ov} \) encompasses all forms of mixing occurring close to the core boundary. If CMB is induced via rotational shears between the core and the envelope, a dependence between the amount of CMB and the rotation rate is expected. In Fig. 15 the inferred extent of the overshoot zone relative to the core size is plotted as a function of the near-core rotation rate from \( \Omega = 2\pi f_{rot} \), scaled by \( \sqrt{G m_{cc}/r_{cc}^3} \), where \( G \) is the gravitational constant. No evidence is found that the CMB increases with a faster rotating near-core region\(^1\). To fully rule out the connection between rotation and the extent of the overshoot zone, the rotation of the convective core itself needs to be measured. Saio et al. (2021) have derived the rotation of the convective core in 16 rapidly rotating \( \gamma \) Dor stars from

\[^1\] No scaling of \( \Omega \) also does not reveal a correlation.
the sample of Li et al. (2020) by studying the coupling between inertial modes in the convective core and $g$ modes in the radiative envelope. These authors find only small differences with the rotation rates derived from $g$ modes in the TAR framework for the majority of stars.

### 4.2. Angular momentum of the sample

The AM of a star, $J$, is defined as

$$ J = \int r^2 \Omega(r) \, dm. $$

For eight stars in our sample, Van Reeth et al. (2018) have measured the ratio of the near-core rotation rate to the surface rotation rate, suggesting that all eight stars are quasi-rigidly rotating. In addition, Siau et al. (2021) find the γ Dor stars in their sample to be rotating nearly uniformly as well. Therefore, assuming

$$ \Omega(r) $$

is constant throughout the star and that typical mass loss in F-type stars ($M = 10^{-13} \, M_{\odot} \, yr^{-1}$) is too small to carry away significant amounts of AM from the star, we can infer the rotation rate at any point in time since $J$ is constant. Figure 16 shows the fraction of AM in the convective core, compared to the total AM of the whole star, $J$, as a function of stellar age $\tau$. Furthermore, two examples of the evolution of the AM of the convective core\(^2\), $J_{cc}/J$ for KIC 2710594 ($\sim 1.5 \, M_{\odot}$) and KIC 7434470 ($\sim 1.9 \, M_{\odot}$) when rigid rotation is assumed, are shown.

Mombarg et al. (2019) observed that stars with detected Rossby modes are situated across the entire MS (based on $X_c/X_{\text{mi}}$), which is in line with our findings. In Fig. 17 we show

\(^2\) $J_{cc}$ is computed by discretising the integral in Eq. (10), i.e. $J_{cc} = \Omega \sum r^2 dm$, where $r$ runs over the cells in the model below the convective core, and $r$ and $dm$ are the central radius and enclosed mass of a cell, respectively.
Fig. 10. Comparison between the $\Pi_0$ values derived by Van Reeth et al. (2016, 2018) ($\Pi_0^{\text{obs}}$, simultaneously with $f_{\text{rot}}$) vs. the values found from the best models presented in Table 3 of this paper ($\Pi_0^{\text{model}}$). The grey dashed line indicates perfect correspondence. The outlier KIC 11099031 is indicated in red.

Fig. 11. Derived masses and overshoot parameters for all stars in our sample from the GYRE models. For comparison, the inferred overshoot parameters of low-mass stars by Deheuvels et al. (2016) (solutions with microscopic diffusion, where we have used $\alpha_{ov} \approx 10 f_{ov}$) are plotted in grey.

4.3. Mode interaction in KIC 12066947

One particularly interesting star in our sample is KIC 12066947. It shows just one characteristic dip in the period spacing pattern at 0.38 days. Such a single dip is not expected to be caused by a chemical gradient because this introduces multiple dips (Miglio et al. 2008). Recently, Saio et al. (2021) were able to reproduce the sharp dip observed in the period spacing pattern of this star, using the formalism by Lee & Baraffe (1995) to compute the coupling between $g$ modes in the radiative envelope and an inertial mode in the convective core. To exclude the scenario of constant envelope mixing combined with a chemical gradient in the core boundary layer as a possible second explanation, we again repeat Step 5 (Sect. 3), but with extremely inefficient envelope mixing: $D_0 = 0.05 \, \text{cm}^2 \, \text{s}^{-1}$. As can be seen from the best pulsation model selected from those
**Fig. 15.** Extent of the overshoot region with respect to the radius of the convective core as a function of the angular rotation rates from Van Reeth et al. (2016), scaled with frequency $\sqrt{Gm_{cc}/r_{cc}^3}$, where $m_{cc}$ and $r_{cc}$ are the core mass and radius, respectively. The symbol size is indicative of the stellar mass.

**Fig. 16.** Fractional AM of the convective core to total AM, assuming rigid rotation throughout the MS. Stars with detected Rossby modes are plotted as triangles and highlighted in red. The symbol size is indicative of the mass. The grey symbols indicate the predicted evolution of $J_{cc}/J$ (assuming rigid rotation) for KIC 2710594 (upward triangles) and KIC 6953103 (downward triangles).

**Fig. 17.** Near-core rotation rates ($\Pi_0$) from Van Reeth et al. (2016, 2018) as a function of age $\tau$ (this work). Stars with detected Rossby modes are shown as red triangles. The symbol size is indicative of the mass.

**Fig. 18.** Distributions of near-core rotation frequencies. Red: distribution of the present near-core rotation frequencies from Van Reeth et al. (2016, 2018). Black: distribution of the rotation rate near the ZAMS, assuming rigid rotation throughout the MS. Grey: normalised distribution from Li et al. (2020).

**Fig. 19.** Best-fitting model with $D_0 = 0.05 \, \text{cm}^2 \, \text{s}^{-1}$ to the observed period spacing pattern of KIC 12066947 (black dots; Van Reeth et al. 2016). For reference, the best fit with the standard $D_0 = 1.0 \, \text{cm}^2 \, \text{s}^{-1}$ used in this work is shown in grey.

computed from the best stellar models according to C-3PO (see Fig. 19), a low $D_0$ introduces a dip in the pattern around the observed dip in period spacing close to 0.38 days. However, the additional theoretically predicted dips are not observed. A rotation rate of $25^{+0.09}_{-0.10} \, \mu \text{Hz}$ for KIC 12066947 has been measured by Van Reeth et al. (2016). Assuming a uniform rotation profile at $25 \, \mu \text{Hz}$, Ouazzani et al. (2020) have computed the radial order at which the interaction between inertial and gravito-inertial modes occurs. According to the parameters derived for KIC 12066947 in this work, the star is most similar to the mid-MS model from Ouazzani et al. (2020), for which the mode interaction is estimated to occur at $n_{pg} = -44$. The dip in the period spacing pattern occurs at $n_{pg} = -44$; therefore, if the dip is caused by interaction between gravito-inertial and pure inertial modes, it should occur close to the dip. Hence, the observed dip in the period spacing pattern of KIC 12066947 is most likely caused by mode interaction, confirming the results by Ouazzani et al. (2020) and Saio et al. (2021).

4.4. Comparison with Mombarg et al. (2019)

In Fig. 20 we compare the MLE for $M_\star$, $X_c$, and $f_{ov}$ from C-3PO (this work) with those from Mombarg et al. (2019). Several key differences between the NN methodology in this work and theirs should be noted while evaluating the comparison, as summarised in Table 4. Keeping these differences in mind, the agreement among the estimated parameters is adequate, given the uncertainties on the parameter estimation. This is not the case for all stars in terms of their masses, however. The mass estimates from the NN methodology are in general lower than those of Mombarg et al. (2019). This is not a consequence of the more
In this paper we have constructed a forward-modelling scheme for gravi-to-inertial modes in γ Dor stars, and used it to estimate the stellar mass, the central hydrogen mass fraction, and the overshooting parameter. We have eliminated the need for large grids of stellar models by training a dense neural network on a coarse grid of stellar evolution and pulsation models, and predict the corresponding oscillation periods \( n \in [15, 91] \) and the luminosity, effective temperature, and surface gravity, given the mass, hydrogen mass fraction in the core, metallicity, efficiency of core-boundary mixing and radiative envelope mixing, and rotation rate. All of the input parameters of the network have been varied within appropriate ranges of γ Dor stars, making it a versatile tool for estimating stellar parameter ranges with minimal computational effort. The C-3PO neural network, comprising eight different subnetworks, has been applied to a sample of 37 γ Dor stars for which period spacing patterns have been detected by Van Reeth et al. (2016). For \( T_{\text{eff}} \) and log \( g \) we relied on the measurements from Van Reeth et al. (2015), and have derived luminosities for the sample using Gaia DR2 distances from Bailier-Jones et al. (2018).

Using the mass and \( X_C \) estimates of C-3PO, we have computed small grids of stellar pulsation models for each star in order to further constrain the overshoot \( f_{\text{ov}} \) as well. We find no evidence that the core boundary mixing efficiency correlates with stellar mass, age, or rotation rate. However, we do observe that stars with larger core masses tend to have larger overshoot regions. Furthermore, we find that Rossby modes are only detected in the more evolved stars in our sample, which is only seen when the actual stellar age is used instead of \( X_C/X_{\text{ini}} \). However, a much larger sample is needed to conclude whether Rossby modes are indeed not observed for stars younger than about 1 Gyr. Li et al. (2020) compiled a sample of 611 γ Dor stars, 83 of which have observed Rossby modes. Many of these 611 stars lack spectroscopic observations; therefore, the MLEs may in general be less constrained.

To compute the mode periods we relied on the traditional approximation of rotation (TAR), which assumes spherical symmetry and loses its validity for rapidly rotating stars deformed by the centrifugal force (cf. Mathis & Prat 2019, for an improved description of the TAR in that case). In Fig. 21, the distribution of the critical Roche frequency for the stars in our sample is shown. Inspecting the quality of fit for the star with the largest fraction of \( \Omega/\Omega_{\text{crit, Roche}} \), namely KIC 12066947 (~80%), suggests that the TAR is still able to reproduce the observed patterns to a satisfactorily level, in line with the findings by Henneco et al. (2021). However, our models are not able the reproduce the sharp dip in the observed pattern, suggesting it is caused by resonances between gravito-inertial and pure-inertial modes (Ouazzani et al. 2020; Saio et al. 2021). An improved formalism of the TAR, taking into account the centrifugal deformation, has been developed by Mathis & Prat (2019). The inclusion of the centrifugal force in the pulsation computations of γ Dor stars has a smaller effect on the predicted values for the periods than the inclusion of stratified envelope mixing profiles due to radiative levitation (Mombarg et al. 2020) or other mixing phenomena, although for lower radial orders the effect of the centrifugal force should be observable in long time-base, space-based photometry (Henneco et al. 2021).

In the stellar structure and evolution models used in this work, the effect of atomic diffusion is neglected. Mombarg et al. (2020) demonstrated for two slowly rotating γ Dor stars that this process (including radiative levitations) can lead to significant differences in the derived mass, age, and near-core boundary mixing. The obtained period spacing pattern of the best-fitting model for KIC 9751996 suggests that we are underestimating...
$D_0$. The need for more envelope mixing supports the conclusion of Mombarg et al. (2020) who find that models without atomic diffusion better reproduce the observed mode periods for this particular star, if other forms of envelope mixing are able to counteract the effects of atomic diffusion. Even though the use of a network greatly decreases the number of required stellar models in the modelling, doing the full radiative levitation calculations in MESA still requires a large amount of computation time. The modelling of the sample in this work with atomic diffusion (including radiative levitation), as well as a non-constant parametrised mixing profile in the radiative envelope will be taken up in a future paper.

Notes. The ‘Reliable $A_V$’ flag indicates whether a reliable estimation of the extinction could be made with the Bayerstar2019 extinction map. Stars for which no reliable estimation could be made according to the Bayerstar2019 map are relatively close by, and therefore the extinction is expected to be minimal. For the stars flagged with an asterisk (*) the luminosity is inconsistent with the pulsations, and its value is therefore not used in the modelling.
Appendix B: Best-fitting parameters from neural network

Table B.1. Best-fitting parameters of the model predicted by the C-3P0 neural network.

Appendix C: Distribution of the residuals

In Fig. C.1 we show the residuals ($P_{\text{true}} - P_{\text{pred}}$), per radial order, of the NN on the grid of 38915 stellar pulsation models used for training and validation.

Appendix D: Best-matching period spacing patterns

In this appendix we present the best-fitting period spacing patterns found with C-3P0 (in red) and GYRE (in blue) for all stars in our sample. The observed period spacing patterns are taken from Van Reeth et al. (2015), where the uncertainties are typically smaller than the symbol size. Missing radial orders are indicated by dashed lines. As only the mode periods are fitted, these values are also indicated by dashes at the bottom or top of each panel. Furthermore, in Fig. D.1 we show the distribution of radial orders. A similar distribution is found compared to the one from Li et al. (2020, their Fig. 17).

Appendix E: Test with $D_0 = 0.05 \text{ cm}^2 \text{s}^{-1}$

In this appendix we show the result of the modelling of KIC 11294808, where we have fixed $D_0 = 0.05 \text{ cm}^2 \text{s}^{-1}$ instead of $D_0 = 1 \text{ cm}^2 \text{s}^{-1}$ used in the rest of the paper.

Appendix F: Effect of including Gaia luminosities on the derived mass

In Fig. F.1, we show the difference in inferred stellar mass when we do not include the luminosity from Gaia DR2 in our modelling procedure.
