1. Introduction

In recent years, the interest of the scientific community in studies of the behavior of magnesium and its alloys in various environments, and in the development of new materials based on magnesium for biomedical purposes, has sharply increased [1]. This interest is promoted by the biocompatibility of magnesium, the possibility of its use for biodegradable devices and in implantology, and, finally, by the attractive mechanical properties of magnesium alloys. Additionally, the most highly demanded property of magnesium-based materials is their antibacterial potential, since infections are one of the most unfavorable complications associated with the implantation of any device. At the same time, until recently, the widespread use of magnesium alloys in different corrosive environments, including physiological liquids, was inhibited by its high degradation, leading to the release of hydrogen and an increase in the pH of the liquid medium. In addition, the microbiologically induced corrosion of metals usually contributes to their destruction. The rapid and weakly controllable degradation rate of magnesium and its alloys greatly hampers the clinical use of these materials. Therefore, significant efforts are currently
being made in analyzing the mechanism of antibacterial activity of magnesium-based alloys [2–5], and finding the ways to slow down the rate of degradation. Among the most promising options for protection against degradation are magnesium alloying [6–8], the use of particles of magnesium or magnesium alloys as fillers for polymer matrices [9–11], deposition of protective layers on magnesium alloy substrates [12], and the use of treatments of magnesium alloys, leading to a superhydrophobic state in the surface [13–20].

Recently, we have shown [17] that the appropriate selection of a laser treatment regime for obtaining the desired texture and chemical composition of the surface layer makes it possible to create a superhydrophobic coating on a magnesium alloy that exhibits satisfactory corrosion resistance even after prolonged immersion in a 0.5 M sodium chloride solution. In this work, we investigate the degradation and anticorrosive properties of fabricated superhydrophobic coatings under conditions of microbiological corrosion when immersed in bacterial dispersions of bacteria cells *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* in phosphate-buffered saline.

2. Materials and Methods

2.1. Sample Preparation

We used magnesium alloy MA8 with the chemical composition (in weight %) Mn 1.65, Ce 0.25, Fe 0.05, Si 0.05, Ni 0.007, Al 0.1, Cu 0.05, Be 0.002, Zn 0.04, Mg balance, to fabricate superhydrophobic samples for the studies described in this paper. Flat sheets with a thickness of 2 mm were cut into samples with a size of $20 \times 20$ mm$^2$. To impart the superhydrophobic state onto the samples’ surfaces, we used a strategy based on attaining hierarchical roughness on the surface, as achieved by laser texturing, and on surface energy reduction via deposition of a hydrophobic agent. Surface texturing was performed using nanosecond laser treatment through the laser processing regimes described in our recent paper [17]. The selection of the regimes was based on the best corrosion protection properties of samples during prolonged contact with 0.5 M NaCl aqueous solution. To perform the laser processing of the samples, we used an Argent-M laser system (LLC “LTC”, St. Petersburg, Russia) with an IR ytterbium fiber laser (wavelength of 1.064 µm, nominal power 20 W, a beam waist of 40 µm), and a RAYLASE MS10 2-axis laser beam deflection unit (RAYLASE GmbH, Wessling, Germany). The laser beam used for the raster scanning of the sample was characterized by the following parameters: fluence 1.5 J/cm$^2$, line density 400 mm$^{-1}$, linear scanning rate 100 mm/s, pulse duration 4 ns, repetition rate 1000 kHz. Laser treatment was performed at a temperature of 20–25 °C and relative humidity of 40–50%. After the laser treatment, the samples were thoroughly washed with deionized water to remove surface micro- and nanoparticles that were weakly adhering to the sample.

To attain a superhydrophobic state on the surface, the laser-treated samples were first subjected for 1 h to ozone-assisted UV irradiation, and then hydrophobized by exposure to saturated vapors of methoxy-[3-[(2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-pentadecafluorooctyl)oxy]-propyl]-silane in a sealed vessel for 1 h at 105 °C, and dried for 1 h in an oven at 150 °C. The obtained surfaces had water contact angles of more than 170 °C and roll-off angles below 3 °. The details of the hydrophobization procedure, with a substantiation of each stage necessary to derive a superhydrophobic state with extremely high contact angle, low roll-off angle, and satisfactory durability, are discussed in [21].

2.2. Analysis of Bactericidal Properties of the Superhydrophobic Magnesium Substrates

In this study, the bactericidal activity of superhydrophobic magnesium alloy substrates was studied with respect to two pathogenic strains, *Pseudomonas aeruginosa* (*P. aeruginosa*) and *Klebsiella pneumoniae* B-811 (*K. pneumoniae*). The strains were obtained from the State Collection of Pathogenic Microorganisms and Cell Cultures (GKPM-Obolensk, Obolensk, Russia), registration numbers B-8050 for *P. aeruginosa* and B-7707 for *K. pneumoniae*. Phosphate-buffered saline (PBS) purchased from VWR Life Science AMRESCO (Radnor, PA, USA) was used as a dispersion medium. This choice of dispersion medium is related to the recently detected significant effect of the nutrient dispersion medium on the corrosion activity of
metals immersed in bacterial dispersion, which in turn modulates the antibacterial properties [22,23]. Using PBS, which does not contain protein nutrients, precludes the disturbing influence of protein nutrients on the antibacterial efficiency of magnesium substrates. To prepare the bacterial suspensions, an overnight bacterial culture was introduced into the PBS and incubated for 18 h at 37 °C. For the experiments, dispersions of bacterial cells with an initial titer of $10^7$–$10^8$ colony-forming units (CFU) per mL were used.

To test the bactericidal properties with respect to planktonic forms of different strains, superhydrophobic plates were placed in a separate sterile cup for each strain, and 40 mL of the each bacterial suspension was poured into its corresponding cup. The cups were stored at room temperature for 48 h. To evaluate the bactericidal action of the plates in contact with the dispersion, after a predefined time of contact, an assay of a bacterial suspension with a volume of 0.5 mL was taken from each cup. Ten-fold dilutions were prepared, then 0.1 mL was taken from each dilution and evenly distributed over the surface of Müller-Hinton agar in Petri dishes. After incubation at 37 °C for 24 h, the bacterial titer was determined by counting the formed colonies. To quantify the effect of contact between the bacterial suspension and the superhydrophobic MA8 plate, for each strain and each contact duration, the obtained titer was normalized to the initial titer in the dispersion.

Additionally, for each strain and each contact duration, a second assay (1 mL) was used for the determination of magnesium egress into PBS, as described below.

2.3. Determination of the Concentration of Mg$^{2+}$ in a Dispersion Medium

The assay containing 1 mL of bacterial dispersion was poured into an Eppendorf tube and centrifuged at 14,000 rpm for 10 min. The liquid phase after centrifugation was used to determine magnesium content in the PBS via mass spectrometry analysis, using the inductively coupled plasma mass spectrometer (ICP-MS) Agilent 7500CE (Agilent Technologies, Santa Clara, CA, USA).

Concentrated nitric acid (65 wt.%) was added to each sample in order to obtain a 0.01 M solution. Then, the digestion of samples was carried out at 60 °C for 40 min. The nitric acid used in the digestion was of high purity (Sigma-Aldrich, Burlington, VT, USA). All digestion samples were prepared in a laminar flow cabinet. The resulting solution was injected directly into the instrument. Laboratory blank samples were also analyzed via the same digestion method. The average magnesium concentration in blank samples was then subtracted from the measured concentration in each digest to give the final reported concentration of that element. Each sample was analyzed 3 times in order to assess possible drift effects. Standard solutions for calibration with respect to magnesium were prepared by diluting multi-element stock solutions (Agilent Technologies multi-element solution, 10 mg/L) with Milli-Q water containing 0.6% (0.01 M) nitric acid. The calibration scale was from 1 µg/L to 1 mg/L, $R^2 = 0.999$.

2.4. Characterization of Surface Morphology, Chemical and Phase Composition

Phase analysis of the laser-treated samples was performed with the X-ray diffractometer Empyrean (Panalytical BV, Almelo, The Netherlands) using Ni-filtered Cu K$_{α1}$-radiation in standard Bragg–Brentano (reflection) geometry. The diffraction patterns of the as-treated samples were dominated by very strong reflections from the bulk Mg-alloy; the identification of phases in the surface layer was complicated by both the very small amount of material and the plausible texture effects, making interpretation difficult. Subsequently, material from the surface was collected by gentle mechanical scratching, thus minimizing the contribution of the bulk material and decreasing the influence of texture.

The morphology and the elemental composition of the samples were studied by field-emission scanning electron microscopy and energy-dispersive X-ray spectroscopy (EDS) on an FIB-SEM Nvision 40 workstation (Zeiss, Oberkochen, Germany) equipped with an X-MAX energy-dispersive detector (Oxford Instruments, High Wycombe, UK). The SEM images were recorded in secondary electron detection mode at accelerating voltages of 2–5 kV. EDS microanalysis was performed at a 10 kV accelerating voltage.
The infrared spectra of the samples were investigated using the Fourier-transform infrared (FTIR) spectrometer Nicolet 6700 (Thermo Scientific, Waltham, MA, USA), with a specular apertured grazing angle (SAGA) accessory and a mercury cadmium telluride (MCT) detector cooled with liquid N\textsubscript{2}. The angle of incidence for SAGA was 80°, and the diameter of the circular sampling area was 8 mm. The spectra were recorded at a resolution of 4 cm\textsuperscript{-1}. All the spectra were derived from the result of an average of 128 scans.

2.5. Characterization of Surface Wettability and pH of the Dispersion Medium

The measurement of pH in bacterial dispersions after a predefined time of contact between the superhydrophobic sample and the dispersion was performed using the micro-electrode ESK-10614 (LLC Measuring Technology, Moscow, Russia).

The wettability of the coatings just before and after contact with the bacterial dispersions was characterized by measuring the contact and roll-off angles. Digital image processing of the sessile droplets and Laplace fit optimization for determining the droplet shape parameters were used to calculate the contact angles [24]. The roll-off angle of the sessile droplets was defined by gently tilting the substrate until the droplet started to roll over the surface. Both the contact angles and roll-off angles were measured for 15 µL droplets at least 10 different surface locations for each sample.

2.6. Characterization of Electrochemical Properties of Surfaces after Contact with Bacterial Suspensions

The electrochemical properties of the test surfaces were studied using an electrochemical workstation Elins P50x (Elins, Chernogolovka, Russia) equipped with a frequency–response analyzer (FRA 24M) for electrochemical impedance spectroscopy measurements. The measurements were carried out at 25 °C in a three-electrode cell (PAR K0235 (Princeton Applied Research, Oak Ridge, TN, USA)), with a 0.5 M NaCl aqueous solution as the electrolyte. A silver/silver chloride electrode (Ag/AgCl) filled with saturated KCl solution served as a reference electrode, and a Pt mesh served as a counter electrode.

To study the effect of the corrosion degradation of superhydrophobic samples in bacterial dispersions, the samples were immersed in the dispersion for up to 48 h. The corrosion degradation was analyzed via the corrosion current and the impedance spectra. For the measurements, the sample was taken off the dispersion, rinsed with distilled water, and placed into the three-electrode electrochemical cell as a working electrode. The measurement of polarization curves was performed after 60 min of equilibration of the sample to a 0.5 M sodium chloride aqueous solution. The potentiodynamic polarization curves were registered at a scan rate of 1 mV/s in the applied potential range of −150 to +300 mV (with respect to open circuit potential). The corrosion potential, $E_{\text{cor}}$, and current, $J_{\text{cor}}$, were derived from the potentiodynamic polarization curves after Tafel extrapolation.

A sinusoidal perturbation signal with an amplitude of 10 mV (with respect to open circuit potential) was used for the electrochemical impedance spectroscopy measurements. Impedance spectra were acquired in the frequency range from 0.05 Hz to 100 kHz via a logarithmic sweep (20 points per decade).

3. Results and Discussion

3.1. Morphology and Wettability of Superhydrophobic Coating

The as-fabricated superhydrophobic coating on the magnesium alloy MA8 is characterized by hierarchical roughness and a low surface energy, which resulted in an apparent contact angle of 171 ± 1° and roll-off angle of 3 ± 1°. The analysis of the coating’s behavior when in continuous contact with deionized water showed the extremely low degradation of the superhydrophobic properties, with the maintenance of contact angles above 170° and roll-off angles below 5°. The morphology of the textured surface of this coating before contact with the corrosive liquid medium is shown in Figure 1a,b. The immersion of this coating into the bacterial dispersions in PBS caused notable morphology changes (Figure 1c–h) because of the highly corrosive activity of the liquid medium.
The as-fabricated superhydrophobic coating on the magnesium alloy MA8 is characterized by hierarchical roughness and a low surface energy, which resulted in an apparent contact angle of 171 ± 1° and roll-off angle of 3 ± 1°. The morphology of the textured surface of this coating, when in continuous contact with deionized water showed the extremely low degradation of the coating into the bacterial dispersions in PBS. A comparison of the SEM images allows us to conclude that the freshly prepared sample demonstrates a dense structure consisting of micro- and nano-elements (Figure 1b), while contact with biological liquids causes structural looseness of the superhydrophobic surface, differs from the original surface, and is different for the samples contact-intrinsic features of the superhydrophobic surface, although it preserves the multimodal corrosion mechanism of magnesium dissolution. The replacement of water with an electrolyte with a complex composition (for example, biological liquids) modifies the corrosion process and diversifies the corrosion products, as well as the kinetics, type, and degree of surface degradation.

It is well documented in the literature that bare magnesium and its alloys are characterized by a high intrinsic corrosion propensity in the aqueous phase. The anodic and cathodic electrochemical reactions of magnesium in an aqueous solution are presented by the equations:

\[
\begin{align*}
\text{anodic reaction (1)}: & \quad \text{Mg} & \rightarrow & \text{Mg}^{2+} + 2\text{e}^- \\
\text{cathodic reaction (2)}: & \quad 2\text{H}_2\text{O} + 2\text{e}^- & \rightarrow & \text{H}_2\uparrow + 2\text{OH}^- \\
\text{reaction (3)}: & \quad \text{Mg}^{2+} + 2\text{e}^- & \rightarrow & \text{Mg} \\
\text{reaction (4)}: & \quad \text{Mg(OH)}_2 + \text{H}_2\uparrow & \rightarrow & \text{Mg(OH)}_2 \text{H}_2\uparrow \\
\text{reaction (5)}: & \quad \text{Mg(OH)}_2 & \rightarrow & \text{Mg}^{2+} + 2\text{OH}^- \\
\text{reaction (6)}: & \quad \text{Mg} + 2\text{H}_2\text{O} & \rightarrow & \text{Mg}^{2+} + 2\text{OH}^- + \text{H}_2\uparrow \\
\text{reaction (7)}: & \quad \text{Mg(OH)}_2 + \text{H}_2\uparrow & \rightarrow & \text{Mg(OH)}_2 \text{H}_2\uparrow \\
\end{align*}
\]

Figure 1. SEM images illustrating the surface morphology of the superhydrophobic coating on MA8 magnesium alloy:
(a,b) freshly prepared; (c,d) covering film after 48 h of immersion in bacterial dispersions of K. pneumoniae in PBS; (e,f) covering film after 48 h of immersion in bacterial dispersions of P. aeruginosa in PBS; (g) microrods formed after 48 h of immersion in bacterial dispersions of K. pneumoniae in PBS; (h) microrods formed after 48 h of immersion in bacterial dispersions of P. aeruginosa in PBS.
The analysis of the SEM images shows the presence of similar features, such as bundles of microrods (Figure 1g,h). However, the newly formed surface layer covering the intrinsic features of the superhydrophobic surface, although it preserves the multimodal surface texture, differs from the original surface, and is different for the samples contacting different bacterial dispersions. A comparison of the SEM images allows us to conclude that the freshly prepared sample demonstrates a dense structure consisting of micro- and nano-elements (Figure 1b), while contact with biological liquids causes structural loosening, either changing to a sponge-like morphology in the case of *K. pneumoniae* (Figure 1d), or forming a doughy nanostructured layer, in the case of *P. aeruginosa* (Figure 1f). To understand the mechanism of the formation of these newly developed surface features (the microrods and the covering film), we studied the morphology of the surface of the fabricated coatings after contact with PBS free from bacterial cells. The microrods and covering films formed in the latter case as well. As will be shown below in Section 3.2, the elemental composition of the microrods was the same for both bacterial dispersions and PBS free from bacteria. These data indicate that the impact of bacterial metabolites on microrod formation is too weak (if any) to be detected experimentally, and the main mechanism of microrod formation is related to the chemical interaction of magnesium with components of PBS.

It is well documented in the literature that bare magnesium and its alloys are characterized by a high intrinsic corrosion propensity in the aqueous phase. The anodic and cathodic electrochemical reactions of magnesium in an aqueous solution are presented by the equations

\[
\begin{align*}
\text{Mg} & \rightarrow \text{Mg}^{2+} + 2e^- \quad \text{anodic reaction} \ (1) \\
2\text{H}_2\text{O} + 2e^- & \rightarrow \text{H}_2 \uparrow + 2\text{OH}^- \quad \text{cathodic reaction} \ (2)
\end{align*}
\]

The whole electrochemical corrosion process is described by the reaction

\[
\text{Mg} + 2\text{H}_2\text{O} \rightarrow \text{Mg(OH)}_2 + \text{H}_2 \uparrow \quad (3)
\]

which can be easily detected via the release of hydrogen from and alkalization of the liquid phase. An additional indication of the corrosive process at pH > 10.5 is the precipitation of magnesium hydroxide [2]. The precipitated magnesium hydroxide forms a layer on the magnesium’s surface; however, this layer does not protect the surface against further magnesium dissolution. The replacement of water with an electrolyte with a complex composition (for example, biological liquids) modifies the corrosion process and diversifies the corrosion products, as well as the kinetics, type, and degree of surface degradation [2,25]. The presence of bacterial cells in the liquid medium contacting the metal surface can either enhance the corrosion process, due to combination with microbiologically induced corrosion, or suppress the corrosion degradation [22,26]. The morphological features of the surfaces of the superhydrophobic MA8 after 48 h of contact with dispersions of *P. aeruginosa* and *K. pneumoniae* show some similarities, such as bundles of microrods, formed as a result of the interaction of magnesium with PBS. To analyze the degradation of the magnesium alloy MA8 with a superhydrophobic coating during immersion in PBS or bacterial dispersions, we studied the variation in the properties of both the substrates and the liquid medium.

Let us first consider the variation in the superhydrophobic sample’s wettability over 48 h of contact with liquid medium. It was found that just after the withdrawal of the sample from the cup with PBS free of bacterial cells, the wettability was notably different from that of the sample before contact with the corrosive medium. The measured contact and roll-off angles became 163.3 ± 1.0° and 14.3 ± 3.9°, respectively. However, washing with a water jet, followed by 30 min of drying in an oven at T = 180 °C, led to the nearly complete recovery of the superhydrophobic state, with a contact angle of 170.7 ± 1.0° and roll-off angle of 3.5 ± 2.0°. The analysis of the variation in the wettability of superhydrophobic samples during contact with bacterial dispersions was performed for samples subjected to immersion in bacterial dispersions, followed by immediate washing via water jet, and
oven-drying at T = 180 °C for 30 min. Such immediate heat treatment after the sample’s withdrawal from the dispersion was performed to ensure complete bacterial decontamination. The measured wettability of the sample after the described procedure indicated the preservation of a superhydrophobic state for all studied samples in both bacterial strain dispersions. As an example, Figure 2 shows the values of the contact and roll-off angles for one set of experiments using the dispersion of *K. pneumoniae* and immersion for 1 to 48 h. Two values are given for each immersion time, one corresponding to the sample before immersion (blue symbols) and the other showing the sample after a certain time of immersion (red symbols).

![Figure 2](image)

**Figure 2.** The contact (triangles) and roll-off (circles) angles for the superhydrophobic samples before (blue symbols) and after (red symbols) different durations of immersion in the dispersion of *K. pneumoniae*. A separate freshly prepared sample was used for each immersion duration; that is why the initial values (blue symbols) show some variation.

As can be concluded from an analysis of the presented data, the degradation of the superhydrophobic state for all samples, if indeed there was any, was weak. At the same time, the significant differences in the morphology suggest the modification of the surface layer’s composition during contact with the bacterial dispersions. That is why the second step in our study was related to the analysis of the surface’s composition.

### 3.2. Variation in Surface Composition of a Superhydrophobic Coating

The X-ray diffraction patterns (Figure 3a) of the superhydrophobic samples—one of which (1) had no contact with the corrosive medium, and the other two (2 and 3) of which were immersed for 48 h in bacterial dispersions of *K. pneumoniae* and *P. Aeruginosa*, respectively—are dominated by reflections from MgO. This oxide is formed during the interaction of laser irradiation with the magnesium alloy’s surface in the presence of atmospheric oxygen. In samples 2 and 3, the amorphous material was abundant. Unambiguous phase identification for the other surface phases is difficult due to broad variations in cation composition, the degree of crystallinity, and the hydration of many complex phosphates. Orthorhombic hydrated sodium polyphosphate Na₆P₂O₁₈·6H₂O was observed in sample 2, and in a smaller amount in sample 3. Weak reflections from other crystalline phases were
As can be concluded from an analysis of the presented data, the degradation of the superhydrophobic samples before contact with biological liquids (1) and after 48 h of immersion in dispersions of K. pneumoniae (2), P. Aeruginosa (3), or PBS without bacteria (4). The EDS spectrum (5) was measured for bundles of microrods (such as those in Figure 1g,h), and was characteristic of microrods formed in both PBS dispersions studied, as well in PBS without bacteria.

The EDS spectra (Figure 3b) were measured separately for the rods and the areas free of microrods on the surfaces of samples 2 and 3 in the bacterial dispersions. It was found that the rods’ composition was not sensitive to the type of bacterial cells, and was the same for the two bacterial dispersions in PBS and for PBS free of cells. The main components of the rods were Mg, Na, and K hydrophosphates. The covering films that formed on the superhydrophobic surfaces in two studied bacterial dispersions differ from each other by the amount of phosphorous, potassium, and sodium. Additionally, notably lower peaks corresponding to the components of the very top layer of the superhydrophobic structure, such as silicon and fluorine, were registered by EDS. Jointly with the data of X-ray diffraction, indicating the presence of the amorphous material, a decrease in the height of the F and Si peaks along with the preservation of a superhydrophobic state in the sample indicates the presence of hydrocarbon deposits. Such deposits formed on the surface as a constituent of biofilm, resulting from the interaction of bacterial cells with the superhydrophobic surface. The thicker the newly formed biofilm, the weaker the EDS signal from the superhydrophobic coating. To examine this hypothesis, we measured the FT-IR reflectance spectra of the surface in the 3500–2500 cm\(^{-1}\) range of wave numbers, corresponding to stretching C-H vibrations (Figure 4). Indeed, greater C-H absorption, leading to lower reflectance of IR irradiation from the surface, was detected for the sample in contact with P. Aeruginosa cells in comparison to the sample immersed in K. pneumoniae dispersion. Such behavior, indicating a thicker biofilm in the former case, correlates well with the lower F and Si peaks in the EDS spectra.

The formation of such a biofilm on top of a superhydrophobic surface should affect the bactericidal action of magnesium, with respect to the bacterial cell, the alkalinity of the liquid phase, and the corrosion resistance of the superhydrophobic coating when in contact with bacterial dispersions.

Figure 3. X-ray diffraction patterns (a) and EDS spectra (b) for the superhydrophobic samples before contact with biological liquids (1) and after 48 h of immersion in dispersions of K. pneumoniae (2), P. Aeruginosa (3), or PBS without bacteria (4). The EDS spectrum (5) was measured for bundles of microrods (such as those in Figure 1g,h), and was characteristic of microrods formed in both PBS dispersions studied, as well in PBS without bacteria.
The analysis of the data obtained for both the control bacterial dispersions indicates that the number of living cells weakly increased with time over the 48 h of monitoring. Thus, PBS can be considered as a friendly medium for bacterial cell growth, at least for the studied time. As for the titer of dispersions that was in contact with the superhydrophobic magnesium samples, it was found that the titer of *K. pneumoniae* started to notably decrease only after 12 h of contact. Such reduction in the antibacterial activity of the superhydrophobic plate compared to the bare metal is related to the high protective action of a superhydrophobic surface, which inhibits the transition of ions, charges, and water molecules through the superhydrophobic textured layer, suppresses the adhesion of bacterial cells onto the surface, and significantly decreases the rate of metal dissolution. However, after 48 h, the dispersion can be considered free from bacterial contamination. Since the wettability studies described above indicated the preservation of a superhydrophobic state in the sample after 48 h of contact with the dispersion, and only an insignificant decrease in contact angles and an increase in roll-off angles were shown, the observed bactericidal action is seemingly related to the appearance of a few wetting defects.

**3.3. Antibacterial Activity of Superhydrophobic Coatings in Bacterial Dispersions**

The bacterial activity of the superhydrophobic samples of MA8 alloy immersed in bacterial dispersion, with respect to planktonic forms of *K. pneumoniae* or *P. Aeruginosa*, was estimated by monitoring the evolution of the bacterial titer in the dispersion when the sample was immersed (Figure 5). For comparison, the evolution of the bacterial titer in the control dispersions not in contact with a superhydrophobic surface is presented. The analysis of the data obtained for both the control bacterial dispersions indicates that that the number of living cells weakly increased with time over the 48 h of monitoring. Thus, PBS can be considered as a friendly medium for bacterial cell growth, at least for the studied time.

As for the titer of dispersions that was in contact with the superhydrophobic magnesium samples, it was found that the titer of *K. pneumoniae* started to notably decrease only after 12 h of contact. Such reduction in the antibacterial activity of the superhydrophobic plate compared to the bare metal is related to the high protective action of a superhydrophobic surface, which inhibits the transition of ions, charges, and water molecules through the superhydrophobic textured layer, suppresses the adhesion of bacterial cells onto the surface, and significantly decreases the rate of metal dissolution. However, after 48 h, the dispersion can be considered free from bacterial contamination. Since the wettability studies described above indicated the preservation of a superhydrophobic state in the sample after 48 h of contact with the dispersion, and only an insignificant decrease in contact angles and an increase in roll-off angles were shown, the observed bactericidal action is seemingly related to the appearance of a few wetting defects.

**Figure 4.** FT-IR reflectance spectra for the surfaces of superhydrophobic samples after 48 h of immersion in dispersions of *K. pneumoniae* and *P. Aeruginosa*. The reflectance bands at 2856 cm\(^{-1}\) and 2926 cm\(^{-1}\) correspond to symmetric and asymmetric C-H stretching vibrations in CH\(_2\) groups, while band 2962 cm\(^{-1}\) arises due to asymmetric C-H vibration in the CH\(_3\) group [27] of bacterial cell membranes.
In contrast, the biofilm on top of the superhydrophobic surface that was immersed in a bacterial dispersion of \textit{P. Aeruginosa} additionally inhibited the bactericidal action of the metal. Even after 48 h of contact with the superhydrophobic sample, the titer of \textit{P. Aeruginosa} cells in the dispersion remained as high as 50\% of the initial titer.

An analysis of the literature shows that there is still no consensus on the nature of the anti-bacterial activity of magnesium alloys. The main mechanisms of toxic action discussed in the literature are [2–5]: (1) the high reactivity of Mg in contact with aqueous media, leading to the formation of superoxide ions (O$_2^-$); (2) an excess of magnesium ions in the aqueous medium surrounding the cells, leading to osmotic effects that destroy cell’s membranes; (3) an increase in pH during the corrosion of magnesium in biological media. Additionally, two mechanisms specific to any superhydrophobic material should be taken into account [28–32]: (4) the low adhesion of bacterial cells to the superhydrophobic surface; and (5) the mechanical damage of cell membranes in the cells deposited onto the surface. The analysis of mechanism (1), related to oxidation stress, is beyond the scope and technical capabilities of this study. The antibacterial mechanisms (4) and (5), related to the superhydrophobic state, are significant, but not determinative for the planktonic forms of bacteria. The evolution of the pH in the PBS and bacterial dispersions, as well as the behavior of the Mg$^{2+}$ ions in the dispersion medium, will be discussed in the next section.

3.4. Variation of pH in Dispersion Medium during Its Contact with a Superhydrophobic Sample

To monitor the variation in pH, which can be considered an indicator of magnesium alloy dissolution in both PBS free from bacterial cells and PBS with bacterial dispersions, the magnesium alloy samples were immersed in the liquid, with a ratio of apparent sample surface to liquid volume of 0.8 cm$^2$/mL, as described above. Data on the variation in pH are presented in Figure 6.

![Figure 5. Time evolution of bacterial titer of \textit{K. pneumoniae} (green diamonds) and \textit{P. Aeruginosa} (red triangles) in the bacterial dispersion in contact with the immersed MA8 alloy sample with a superhydrophobic coating (full symbols). Empty symbols show the corresponding variation in the bacterial titer in the control dispersions without immersed samples. The normalized titer was calculated as a ratio of the titer in an assay taken at a given time to the initial titer in the dispersion.](image-url)
After immersing the superhydrophobic sample for 48 h in PBS free from bacterial cells, a rapid increase in the pH of the liquid from 7.4 to 11.4 was detected. Such alkalization takes place due to the cathodic reaction (2).

Here, it is worth noting that the superhydrophobic state of magnesium surface provides notable anticorrosion protection in neutral chloride-containing media. However, a significant pH increase causes the hydrolysis of Si-O and Si-C bonds in the molecules of fluoroxy silane, used here as a hydrophobic agent [21]. Such hydrolysis results in the hydrophobic molecules’ desorption from the surface, and the formation of wetting defects, which act as channels for ion and charge transfers through the surface layer of the sample, and thus cause some degradation of the magnesium alloy.

In the presence of chloride ions in the alkaline solution, the substitution reaction transforms magnesium hydroxide into soluble chloride, which allows for an increase in pH to values higher than pH = 10.5, corresponding to magnesium hydroxide precipitation. In turn, the interaction of the magnesium ions with KH$_2$PO$_4$ monopotassium phosphate or Na$_2$HPO$_4$ disodium phosphate will cause the formation of weakly soluble mixed magnesium, potassium and sodium phosphates, which deposit onto the surface as a covering film (Figure 3b) or as rod-like crystals (Figure 1).

The data presented in Figure 6 for the evolution of pH in bacterial dispersions indicate the partial suppression of the alkalization of the dispersion medium in the presence of bacterial cells. This observed phenomena can be related to the additional protective action of the covering surface film, which grew on the superhydrophobic surfaces in the bacterial dispersions in PBS. At the same time, even in the presence of bacterial cells, the pH reached values as high as pH = 11.0.

The capturing of magnesium by weakly soluble compounds is additionally substantiated by the low magnesium concentration in the liquid medium (Figure 7). Bearing in mind that the concentrations of Mg$^{2+}$ obtained here are notably lower than those discussed in the literature as toxic, and are of the same order as the typical concentrations in cellular liquids [2,33,34], we can exclude from consideration the mechanism of bacteria-killing associated with the osmotic effects of super-high concentrations of magnesium in the systems under consideration.

![Figure 6. Variation in pH with duration of contact between the MA8 alloy sample with the superhydrophobic coating and PBS with or without bacterial cells.](image-url)
The nonmonotonic increase in Mg\(^{2+}\) concentration over time for all three considered liquid media is seemingly determined by the kinetics of the formation of the covering films and the rods on the surfaces of the superhydrophobic samples. Since the superhydrophobic surface is characterized by an increased energetic barrier for the heterogeneous nucleation of the surface phases [35], we observed an increase in the concentration of magnesium ions that reached the saturation levels necessary to start the mass formation of a new phase (Figure 7).

To present more information on the degradation behavior of superhydrophobic surfaces in PBS and bacterial dispersions in PBS, the electrochemical parameters of the superhydrophobic sample will be given in the next section.

### 3.5. Anticorrosion Behavior of Superhydrophobic Coatings

The superhydrophobic coating on the surface of MA8, obtained by laser treatment followed by the chemisorption of fluorooxysilane, functions as a good protective anticorrosive coating that inhibits the evolution of hydrogen and the formation of crystalline hydrates on the surface. The change in the state of such samples and their possible corrosive degradation were quantitatively characterized in Section 3; here, we will use voltammetry and impedance spectroscopy for deeper analysis. The corrosion currents and the spectra of the impedance modulus were measured before and after the immersion of the samples in bacterial dispersion for 1, 2, 3, 6, 12, 24, 36, and 48 h. It is worth noting that high-quality superhydrophobic surfaces are characterized by extremely low corrosion currents and high impedance values at low frequencies. That is why even minor wetting defects on the surface may cause a one order of magnitude variation in the corrosion current and the modulus of impedance. To avoid uncertainty in the initial characteristics of the samples used for this study, we have compared the corresponding characteristics of each sample before and after contact with the bacterial dispersions. Two different samples were used for each duration of immersion and for each type of dispersion. Figure 8 shows the obtained values of corrosion current density and impedance modulus before and after contact with the bacterial dispersion for individual superhydrophobic samples.
The presented data indicate weak changes in the electrochemical parameters of coatings even with prolonged (for 48 h) contact of the magnesium alloy with a corrosive biological environment. In this case, for a majority of samples, no degradation in the anticrosive properties of the coating was detected, however, an increase in the corrosion resistance was indicated by a decrease in corrosion currents and an increase in impedance moduli. The possible mechanisms of the inhibition of biocorrosion on different metal surfaces, including superhydrophobic surfaces, as discussed in the literature earlier [22,36,37], are as follows: (1) the suppression of the growth of corrosive bacteria by antimicrobial drugs; (2) the release of a peptide corrosion inhibitor; (3) the formation of a protective layer in the case of the physiological activity of bacteria or the strong adhesion of bacterial cells to the interface; (4) the formation of a protective layer by corrosion products; finally, (5) the removal of corrosive agents due to the physiological activity of bacteria. Our data allow us to associate the corrosion inhibition in the systems considered here with two factors: Firstly, the formation of a protective layer due to the physiological activity of bacteria. The formation of such a layer, referred to here as a biofilm and containing hydrocarbon components and mixed phosphates of magnesium, potassium, and sodium, is indicated by the data of IR spectroscopy (Figure 4) and EDS (Figure 3b). The second factor is related to the formation of layers of corrosion products—magnesium phosphates. Besides this, the XRD data indicate the precipitation of sodium polyphosphate from the liquid phase onto the superhydrophobic surface. Phosphate coatings, such as the magnesium phosphate or sodium polyphosphates formed by different means, have been repeatedly employed in earlier studies, and have been shown to be able to improve the anticorrosion performance of Mg-based biomaterials [38–42].

4. Conclusions

The bare magnesium alloy MA8 is characterized by low corrosion resistance in different media, leading to the rapid degradation of magnesium-based materials. It was shown in recent studies that the fabrication of superhydrophobic coatings on the surfaces of such materials significantly enhances the stability of the materials against different types of degradation, including the corrosion phenomena. In this study, we have analyzed the behavior and the impact of the interaction of superhydrophobic MA8 samples with different...
corrosive media. Experiments were performed in phosphate-buffered saline solutions and dispersions of bacterial cells \textit{P. Aeruginosa} and \textit{K. pneumoniae} in PBS.

The superhydrophobic samples used were characterized by extremely high initial corrosion resistance values in chloride-containing solutions. The immersion of such samples into bacterial dispersions resulted in notable changes in the morphology of the samples, due to the deposition of corrosion products related to the formation of a covering film, and bundles of rods of magnesium phosphates and mixed magnesium, potassium, and sodium phosphates. Corrosion reactions caused a significant increase in pH and, consequently, bacterial cell killing. It was found that the bactericidal activity of superhydrophobic coatings is dependent on the bacterial strain. It was shown that the mechanism of such dependence is related to the composition and thickness of the film, composed of corrosion products, on the superhydrophobic surface throughout its interaction with the components of the dispersion.

The analysis of the elemental composition of the film covering the superhydrophobic surface indicated negligible amounts of potassium and sodium in the films formed in PBS. In contrast, significant amounts of sodium were found in the surface films grown in bacterial dispersions. Besides this, the films grown on the surface in contact with the dispersion of \textit{P. Aeruginosa} were characterized by greater amounts of hydrocarbon components, which were seemingly formed as a product of cell metabolism in the alkaline conditions, compared to the films on the superhydrophobic surfaces in contact with the dispersion of \textit{K. pneumoniae}. The formation of biofilms and sodium polyphosphate films provided enhanced barrier properties for magnesium dissolution and hence for dispersion medium alkalization, leading to the inhibition of magnesium substrate degradation. The electrochemical data obtained for superhydrophobic samples in continuous contact with the corrosive bacterial dispersions for 48 h indicate a high level of protective anticorrosion properties in the fabricated superhydrophobic coatings, and their ability to partially inhibit the medium alkalization. The corrosion currents for the samples immersed in bacterial dispersions in PBS followed by oven-drying had values of the order $10^{-10}$–$10^{-11}$ A/cm$^2$. These currents are five to six orders of magnitude lower than the currents characteristic of bare alloy, which did not come into contact with the corrosive medium.
