Abstract

Eigenvalues of a density matrix characterize well the quantum state’s properties, such as coherence and entanglement. We propose a simple method to determine all the eigenvalues of an unknown density matrix of a finite-dimensional system in a single experimental setting. Without fully reconstructing a quantum state, eigenvalues are determined with the minimal number of parameters obtained by a measurement of a single observable. Moreover, its implementation is illustrated in linear optical and superconducting systems.

PACS numbers: 03.67.-a, 03.65.Aa, 03.65.Ta

The eigenvalues of a density matrix are fundamental quantities in quantum physics, and characterize many quantum properties, such as coherence and entanglement. Typically, a function of the density-matrix’s eigenvalues allows us to examine features of a quantum state. The von Neumann entropy, for example, is defined as the Shannon entropy of eigenvalues of a density matrix, and have different applications such as thermodynamic entropy [1], optimal compression rate of a quantum state [2], and entanglement measure [3]. Other entropies of eigenvalues, e.g., the Rényi entropy and the Tsallis entropy [4] have curious applications in thermodynamics and statistical mechanics. The entanglement spectrum [5] is equal to that of the measured quantities, this approach is regarded as an eigenvalue determination with minimum information. We call such a method to be minimal. An eigenvalue determination with minimum information is considered to be simple enough, since there is no redundancy. The minimality of information gain is important in quantum systems, from the viewpoint of the information-disturbance relation [11, 12]. Extracting minimal information can lead to suppressing unnecessary disturbance in a quantum state.

Next, let us consider the implementability of eigenvalue determination, with a single setup. In proposed methods [8][10] with the minimality, the kth moment of ρ is measured by the expectation value of an observable under an identically-and-independently-distributed (i.i.d.) state, ρ⊗k. Thus, this approach requires (d − 1) kinds of the experimental settings to determine all the eigenvalues. A single-setup determination is built straightforwardly by a measurement of an information complete positive operator-valued measure (see, e.g., Ref. [13]). We recall that the information completeness is defined by the state-reconstructing ability from statistical measurement data. One can reconstruct a density matrix, via a single experimental setting for such a measurement [14]. However, as pointed out above, this method does not have minimality. An alternative way for obtaining all the moments of ρ with a single setup is to use random unitary operations on a single system [12]. This method is applicable to photon qudits passing through a disordered medium [16], although one must guarantee the uniformity of the random operations.

In this article, we propose a method for measuring the eigenvalues of a density matrix, equipped with both minimality and single-setup implementability. Our proposal for a d-level quantum system consists of a measurement of a single d-valued observable, or equivalently, a measurement of a projection-valued measure (PVM) measurement (P_i)_{i=1}^d, on a d-i.i.d. state, ρ⊗d. Our central idea is to build a specific unitary gate in a multi-partite system. We will show that the characteristic polynomial
of any density matrix $\rho$ is constructed in terms of probability distributions $\text{tr}(P_i \rho^\otimes d)$ as

$$\det(x - \rho) = \sum_{i=1}^{d} m_i(x) \text{tr}(P_i \rho^\otimes d) \quad (x \in \mathbb{R}).$$

(1)

Here $m_i(x) \ (i = 1 \cdots d)$ is a known polynomial of $x$, determined according to the choice of the single observable. From the PVM measurement $(P_i)_{i=1}^{d}$ on state $\rho^\otimes d$, we obtain the probability distribution $\text{tr}(P_i \rho^\otimes d)$. Then, we can calculate all the eigenvalues of $\rho$, via formula (1). This process can be efficiently performed by a classical computer, since the problem is a 1D root finding, simpler than a full matrix diagonalization. Figure 1 is the summary of our proposal. Moreover, we will show methods for implementing our proposal in physical systems.

One of the simple realizations of our approach is to use the anti-symmetrizer (projector on a fermionic ground state). To see this, let us start with some mathematical ingredients. The unitary operator on $H^\otimes k$ associated with a permutation $\sigma \in S_k$ over $k$ integers $\{1, \ldots, k\}$ is

$$U_\sigma |\phi_1 \rangle \cdots |\phi_k \rangle = |\phi_{\sigma(1)} \rangle \cdots |\phi_{\sigma(k)} \rangle,$$

(2)

for $|\phi_i \rangle \in H \ (i = 1, \ldots, k)$. An $m$-cycle $c_m \in S_k$ is a permutation to cycle $m$ distinct integers from $\{1, \ldots, k\}$, with others being fixed. Noting that $\text{tr} \rho^m = 1$, we have

$$\text{tr} (U_{c_m} \rho^\otimes k) = \text{tr} \rho^m \quad (m = 2, \ldots, k),$$

(3)

for any $m$-cycle $c_m$. Thus, each moment of $\rho$ is related to a physical process. An observable for determining $\text{tr} \rho^m$ can be constructed by taking the hermitian part of $U_{c_m}$, as seen in, e.g., Ref. [8]. For a general permutation $\sigma$, we can use the unique decomposition by cycles (see, e.g., Ref. [17]) to obtain

$$\text{tr} (U_\sigma \rho^\otimes k) = \prod_{m=1}^{k} \text{tr}(\rho^m)^{j_m(\sigma)},$$

(4)

where $j_m(\sigma)$ is the number of the $m$-cycles in $\sigma$. For instance, we have $\text{tr} (U_{\sigma} \rho^\otimes 7) = (\text{tr} \rho^2)^2 (\text{tr} \rho^3)$ for $\sigma = (12)(34)(567)$, because $j_2(\sigma) = 2$ and $j_3(\sigma) = 1$, with others being zero.

The anti-symmetrizer on $H^\otimes k$ is defined by

$$A_k = \frac{1}{k!} \sum_{\sigma \in S_k} \text{sgn}(\sigma) U_\sigma \quad (k = 1, \ldots, d),$$

(5)

where $\text{sgn}(\sigma) = \pm 1$ is the sign of $\sigma$. $A_k$ is a projection operator on $H^\otimes k$ ($A_k = A_k^2 = A_k^*$), and has a natural extension on $H^\otimes d$ by $A_k \otimes \mathbb{1}^{d-k}$. Hereafter, we use the same symbol $A_k$ on $H^\otimes d$ and define $A_0$ to be the identity operator on $H^\otimes d$. Using Eqs. (3) and (4), we obtain

$$\text{tr}(A_k \rho^\otimes k) = \frac{1}{k!} \sum_{\sigma \in S_k} \prod_{m=1}^{k} (\mu_m)^{j_m(\sigma)},$$

(6)

with $\mu_m = (-1)^{m-1} \text{tr} \rho^m$. Here we have used $\text{sgn}(\sigma) = \prod_{m=1}^{k} \text{sgn}(c_m)$ and $\text{sgn}(c_m) = (-1)^{m-1}$ for an $m$-cycle $c_m$. Thus, a projective measurement about $A_k$ includes the moments of $\rho$, up to the $k$th order.

Now, we show a way to reconstruct the characteristic polynomial of $\rho$, with Eq. (6). Let us write $\text{tr}(A_k \rho^\otimes k)$ as $a_k$, and formally define $a_0 = 1$. A straightforward calculation of the right-hand-side of Eq. (6) leads to the Newton-Girard formula [17]

$$a_k = \frac{1}{k} \sum_{m=1}^{k} \mu_m a_{k-m} \quad (k = 1, \ldots, d).$$

(7)

Thus, the sequence of $\{a_k\}_{k=1}^{d}$ is equivalent to that of the coefficients of the characteristic polynomial (i.e., elementary symmetric polynomials). To sum up, we obtain

$$\det(x - \rho) = \text{tr}[M(x) \rho^\otimes d],$$

(8)

with $M(x) = \sum_{k=0}^{d} (-1)^k x^{d-k} A_k$. This result is notable, because the characteristic polynomial is described by a single quantum observable $M(x)$. However, we still need to remove the dependence on the continuous variable $x$, to make a single-seup approach possible. The key is the following structure of the anti-symmetrizers. Since a permutation procedure in $A_k$ is a part of $A_l$ when $k < l$ ($S_k \subset S_l$), we find that

$$A_k A_l = A_l A_k \quad (k < l).$$

(9)

Furthermore, the projective property of $A_k$ leads to an eigen-subspace $A_k \subset H^\otimes d$. Therefore, we obtain the inclusion relation for $A_k$:

$$A_d \subset A_{d-1} \subset \cdots \subset A_2.$$  

(10)

We note that $A_1 = H^\otimes d$. Thus, we have an orthogonal decomposition of $H^\otimes d$ as $d \bigoplus_{i=1}^{d} B_i$, with $B_1 = A_d$ and $B_i = A_{d-i+1} - A_{d-i+2}$ ($i = 2, \ldots, d$). The projection
operators $P_i$ onto $B_i$ are then defined by $P_1 = A_d$ and $P_i = A_{d-i+1} - A_{d-i+2}$ ($i = 2, \ldots, d$). They constitute our PVM measurements $(P_i)_{i=1}^d$. By definition, we find that $A_i = \sum_{j=1}^{d-i+1} P_j$. Substituting this formula into Eq. (8), we obtain the practical formula (1) for eigenvalue determination, with

$$m_i(x) = \sum_{k=0}^{d-i+1} (-1)^k x^{d-k}.$$  

(11)

Since the dimension of $A_k$ is $D(k) = d^{d-k} c_k$, the dimension of $B_i$ (i.e., rank $P_i$) is $D(d - i + 1) - D(d - i + 2)$, where we define $D(d + 1)$ to be zero.

We stress that in our approach the use of the anti-symmetrizer $A_0$ is not essential. For instance, the symmetrizer is a direct connection to the coefficients of the characteristic polynomial with the expectation values of the anti-symmetrizers, as shown in Eq. (8).

We also notice that the number of target-state copies may decrease if only partial information on the eigenvalues is needed. In particular, if the number of (approximately) zero eigenvalues, $d_0 < d$ is known a priori (alternatively can be estimated), the present method with $\rho^{\otimes(d-d_0)}$ leads to $(d-d_0)$ predominant eigenvalues. Any prior information other than $d_0$ is not required.

Now, we illustrate the present method in physical systems. We first consider qubits ($d = 2$ and $\mathcal{H} = \text{span}(\{0\}, \{1\})$). The relevant projectors are $P_1 = \langle \Psi_+ | \Psi_+ \rangle$ and $P_2 = \mathbb{1}^{\otimes 2} - \langle \Psi_+ | \Psi_+ \rangle$, with $\langle \Psi_+ | = (|01\rangle - |10\rangle)/\sqrt{2}$. The first example is a linear optical qubit. A quantum state is encoded by horizontal (H) and vertical (V) polarization (i.e., $|H\rangle = |0\rangle$ and $|V\rangle = |1\rangle$). A two-photon interferometer, the Bell-state analyzer (see, e.g., Refs. 19, 20), leads to an implementation of the projectors, as seen in Fig. 2. Although the main part of the eigenvalue determination is the 50:50 beam splitter and the subsequent single-photon detectors, this setting includes a method to prepare a 2-i.i.d. state as well. Let us first explain this preparation stage. The initial photons are horizontally polarized. A series of wave plates is set on each input arm in the interferometer. On every trial, one randomly changes a combination of the wave plates to make an element of SU(2) 21. This procedure probabilistically produces different unitary gates on a polarization state. Thus, one can examine the eigenvalue determination of $\rho = \sum p_r V_r |H\rangle H V_r^{\dagger}$, with $\sum p_r = 1$, $p_r \geq 0$, and $V_r \in SU(2)$. Next, we turn to the determination part. After the interference at the 50:50 beam splitter, either anti-bunching or bunching occurs 19. From the bosonic character of photons, the anti-bunching is related to an anti-symmetric property with respect to the polarization (i.e., $(|HV\rangle - |VH\rangle)/\sqrt{2}$), whereas bunching is relevant to symmetric states. Hence, using two polarizing beam splitters and four threshold detectors ($D_1, D_2, D_3$, and $D_4$), we obtain $tr(P_1 \rho^{\otimes 2})$. When either ($D_1, D_3$) or ($D_2, D_4$) detects photons, this event is counted as $P_1 = 1$. The others correspond to the case $P_2 = 1$.

The main idea in our proposal is to use a projective measurement on a multi-copy of a large quantum state. This technique is applied in photon-qubit experiments 22, 23, to measure non-linear observables such as concurrence. In other words, the present work studies such experimental techniques, from the viewpoint of minimality and single-setup implementability.

Next, we examine a solid-state system, especially a superconducting qubit 22. Let us consider a controlled gate $U_{ZZ} = \exp[-i(\pi/4) H_{ZZ}]$, with $H_{ZZ} = J \sigma_z \otimes \sigma_z$. The 2 × 2 Pauli matrices are $\sigma_x, \sigma_y, \sigma_z$. The qubit-coupling Hamiltonian $H_{ZZ}$ is realized in various systems such as flux qubits 20 and transmon qubits 24, 25. This control gate with single-qubit gates leads to

$$U_D = (\mathbb{1} \otimes U_H)(Z_{-\pi/4} \otimes Z_{-\pi/4}) U_{ZZ}(\mathbb{1} \otimes U_H),$$

(12)

where $U_H = Y_{-\pi/8} Z_{\pi/8} Y_{\pi/8}$, $Z_0 = \exp(i \theta \sigma_z)$, and $Y_0 = \exp(i \theta \sigma_y)$. We find that $U_D |\Psi_+\rangle = |00\rangle$, $U_D |\Psi_\downarrow\rangle = |01\rangle$, $U_D |\Phi_+\rangle = |10\rangle$, and $U_D |\Phi_\downarrow\rangle = |11\rangle$, up to overall phases, where $|\Phi_\downarrow\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$ and $|\Psi_\downarrow\rangle = (|01\rangle + |10\rangle)/\sqrt{2}$. If both of the qubits are detected as $|1\rangle$ after performing $U_D$, the projector $P_1$ is done.

We refer to the extendability of our proposal useful for the implementation in general systems. Using a super-operator $\Xi$ such that $\Xi(\rho^{\otimes d}) = \rho^{\otimes d}$, and its adjoint $\Xi^*$, $tr(\Xi^*(A) B) = tr(A \Xi(B))$, we find that an expansion of the characteristic polynomial is not unique. In contrast to $M(x)$ in Eq. (8), the observable $\Xi^*(M(x))$ may involve operators other than the anti-symmetrizers. Thus, one may perform our proposal, not sticking to the PVM.
measurement. Let us apply this technique to the eigenvalue determination in a linear optical qutrit \((d = 3)\). Our qutrit is a superposition of 3-path (or mode) single-photon states. The corresponding bosonic creation operators are \(a^\dagger_\ell (\ell = 1, 2, 3)\). To represent a 3-i.i.d. state \(\rho^{\otimes 3}\), we need two additional spatial modes \(b^\dagger_1\) and \(c^\dagger_1\), each of which has another spatial-mode-index \(\ell\) for expressing a qutrit state, like \(a^\dagger_\ell\). To simplify the notations, we will denote \(b^\dagger_1\) \((c^\dagger_1)\) as \(a^\dagger_{1+3}\) \((a^\dagger_{1+t_0})\). In our setting, a 3-i.i.d. qutrit enters an interferometer. For each \(\ell\), a mixing among \(a^\dagger_\ell\), \(a^\dagger_{1+3}\), and \(a^\dagger_{1+t_0}\) occurs,

\[
\begin{pmatrix}
    a^\dagger_1 \\
    a^\dagger_{1+3} \\
    a^\dagger_{1+t_0}
\end{pmatrix}
\mapsto \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 1 & 1 \\ 1 & e^{i\frac{2\pi}{3}} & e^{i\frac{4\pi}{3}} \\ 1 & e^{i\frac{4\pi}{3}} & e^{i\frac{2\pi}{3}} \end{pmatrix}
\begin{pmatrix}
    a^\dagger_1 \\
    a^\dagger_{1+3} \\
    a^\dagger_{1+t_0}
\end{pmatrix}. \tag{13}
\]

This transformation (a qutrit quantum Fourier transformation\[29\]) does not alter the bosonic canonical commutation relations, and can be built up by beam splitters and phase shifters\[30\]. The interferometer has nine output ports, each of which is connected to a threshold detector \(D_\alpha (\alpha = 1, \ldots, 9)\). In other words, the detector \(D_\alpha\) is clicked if photons live in the \(\alpha\)th output mode after the transformation\[33\]. We regard a triplet \((D_\beta, D_{\beta+1}, D_{\beta+2})\) as a single detector \(D_\beta (\beta = 1, 4, 7)\). Thus, when at least one element of the triplet is clicked, the logical value of this coarse-graining measurement is true. We can find that three distinct events occur at the outputs in the total apparatus: “bunching” (one of the three coarse-graining detectors is clicked), “anti-bunching” (all the coarse-graining detectors are clicked), and others. The elements of the corresponding positive operator-valued measure (not PVM) are \(Q_1 = (2/3)S_3\) for bunching, \(Q_2 = (S_3/3) + A_3\) for anti-bunching, and \(Q_3 = I^{\otimes 3} - Q_1 - Q_2\) for residues, with the three-body symmetrizer \(S_3\). Now, we take \(\Xi\) as the three-body symmetrizing superoperator, \(\Xi(A) = (1/3!)[\sum_{\sigma\in\Sigma_3} U_{\sigma} A U^\dagger_{\sigma}]\). Then, we find that \(\Xi^\dagger(M)(x) = \sum_{k=1}^{3} m_k(x)Q_k\). The polynomials \(m_k(x)\) can be obtained by straightforward calculations, and does not depend on \(\rho\), like \(m_{\ell}(x)\). In this way, we can reconstruct the characteristic polynomial of a qutrit density matrix, using \(m_k(x)\) and the measurement probabilities \(tr(Q_k\rho^{\otimes 3})\).

Finally, we compare our proposal to an approach proposed by Keyl and Werner\[31\]. They found a single observable for an eigenvalue determination, via a group-theoretic approach (see also Ref.\[32\]). Different from ours, the outcome of the observable in a single-shot measurement is an estimator of the eigenvalues. Their method can be considered to be minimal and implementable in a single setup. However, to obtain high accuracy, their approach requires an \(N\) i.i.d. state \(\rho^{\otimes N}\), with \(N\to\infty\). One has to perform a measurement of a multipartite observable in a many-body system, whose particle number depends on a given accuracy. In contrast, our observable is fixed, once the dimension of a target system is set. Thus, our method could be much simpler, from a technical point of view.

In summary, we showed a simple method for measuring the eigenvalues of a density matrix of a \(d\)-level system in a single setup. We also implemented our proposal in linear optical and superconducting systems. In the present formulation, a characteristic polynomial is reconstructed via quantum measurements. The resultant polynomial is straightforwardly calculated by classical computers. This approach is also applicable to evaluating the energy spectrum of a physical system, like Ref.\[33\]. Thus, our proposal can be used for a practical assessment of quantum features in a physical system.
