ABSTRACT
We employ spectroscopic and photometric data from the Sloan Digital Sky Survey Data Release 7, in a 500-deg^2 region, to understand the evolution of dwarf [∼(M∗ + 2) < Mz < M∗ + 4] galaxies in the Coma supercluster (z = 0.023). We show that in the Coma supercluster, the red dwarf galaxies are mostly concentrated in the dense cores of the Coma and Abell 1367 clusters, and in the galaxy groups embedded in the filament connecting them. The post-starburst (k+A) dwarfs, however, are found in the infall regions of the Coma and Abell 1367 clusters, and occasionally in galaxy groups embedded along the filament, suggesting that strong velocity fields prevalent in the vicinity of deep potential wells may be closely related to the mechanism(s) leading to the post-starburst phase in dwarf galaxies. Moreover, the blue colour of some k+A dwarfs in the Coma cluster, found within its virial radius, suggests that the star formation in these galaxies was quenched very rapidly in the last 500 Myr. More than 60 per cent of all red dwarf galaxies in the supercluster have 0–3 Å of Hδ in absorption, which suggests that a major episode of star formation occurred in a non-negligible fraction of these galaxies, ending within the last Gyr, allowing them to move to the red sequence. The distribution of the blue dwarf galaxies in the Coma supercluster is bimodal in the EW(Hα)–EW(Hδ) plane, where EW represents equivalent width, with one population having very high emission in Hα and some emission in Hδ. A subpopulation of blue dwarfs is coincident with the red dwarfs in the EW(Hα)–EW(Hδ) plane, showing absorption in Hδ and relatively lower emission in Hα. We suggest that a large fraction of the latter population represents the progenitors of the passive dwarf galaxies that are abundantly found in the cores of low-redshift rich clusters, such as Coma.

Key words: galaxies: clusters: general – galaxies: clusters: individual: Coma – galaxies: dwarf – galaxies: evolution – galaxies: star formation.

1 INTRODUCTION
In hierarchical models of structure formation, dwarf galaxies are the ‘building blocks’ of the more massive galaxies. Moreover, the vulnerable nature of these galaxies, which are most abundant in the Universe, makes them an excellent probe for exploring the impact of the environment on evolution of galaxies. A reliable census of dwarfs and detailed knowledge of their properties are required, over a wide range of epochs, to understand the coeval evolution of the large-scale structure and the galaxies therein.

However, unlike their giant counterparts, dwarfs have received little attention in the literature, possibly due to the challenges encountered in observing these faint and low surface brightness galaxies. Nevertheless, studies conducted in the last decade or so have been able to exploit the multiplex gain of wide-field multifibre spectrographs (e.g. Poggianti et al. 2001), while others have targeted the low-luminosity (e.g. Lisker et al. 2007; Smith et al. 2008, and references therein) and low surface brightness (e.g. Chiboucas et al. 2010) galaxy population in nearby clusters (e.g. Lisker et al. 2007; Smith et al. 2008, and references therein).

Large samples of dwarf galaxies have now been exploited to show that passive dwarfs are found only in very dense environments or accompanying a more massive companion (e.g. Haines et al. 2007). Studies of H I gas content in dwarf galaxies do not find any correlation between the H I gas surface density and star formation rate (SFR) (Roychowdhury et al. 2009) or star formation efficiency (Bothwell, Kennicutt & Lee 2009), suggesting that dwarf galaxies are star-forming everywhere. Using H I surface density normalized by stellar mass to quantify star formation efficiency, Bothwell et al. (2009) suggest that mass-dependent quenching mechanism(s) are likely to play a dominant role in galaxy evolution. These results imply that transformations in the observable properties of dwarf galaxies may occur only in specific environments and hence galaxy
populations in the process of transformation should be confined to such regions. The post-starburst (or k+A) galaxies are among the best candidates for such transitional populations.

The k+A galaxies show strong Balmer absorption but lack emission lines in their spectra. Such galaxies are mostly found in and around galaxy clusters at $z \sim 0$ (e.g. Mahajan, Haines & Raychaudhury 2010a) and at higher redshifts (e.g. Dressler & Gunn 1982; Poggianti et al. 2004, but see Goto 2005; Yan et al. 2009 for an alternative view). In the Coma and Abell 2199 superclusters ($z = 0.023$), dwarf galaxies show a stronger relation between the SFR and local galaxy density than is found in the more massive galaxies (Haines et al. 2006; Mahajan et al. 2010a), while elsewhere (Barazza et al. 2009) a strong colour–density relation is found in the Abell 901/902 system ($z = 0.165$). Clusters and rich groups at intermediate and high redshifts ($z \sim 0.5$) have more luminous ($M_V \leq -20$) k+A galaxies, which seem to be missing in rich clusters at $z \sim 0$ (Zabludoff et al. 1996; Poggianti et al. 2004; Nolan, Raychaudhury & Kabán 2007).

In Mahajan et al. (2010a), we combined the optical photometric and spectroscopic data [from the Sloan Digital Sky Survey Data Release 7 (SDSS DR7)] with the 24-μm MIPS to study the star formation and active galactic nucleus activity in galaxies across one of the nearest (∼100 h$_{70}^{-1}$ Mpc) supercluster, namely Coma. In this paper, we use a subset of data from the SDSS DR7 to understand the origin of dwarf k+A galaxies and their evolutionary link to the passive red dwarf galaxies that are observed in abundance in the Coma cluster (Jenkins et al. 2007). We briefly describe the dataset and definition of different galaxy populations in the following section. In Sections 3 and 4, we present our analysis, finally discussing the implications of our analysis in Section 5.

We adopt the concordance cosmology ($\Omega_m = 0.70$; $\Omega_{\Lambda} = 0.30$; $h = 0.7$) for calculating the magnitudes and distances. We note that at the redshift of Coma ($z = 0.023$), our results are independent of the choice of cosmology. Different techniques give varying estimates for the virial radius of the Coma cluster, such that $2 < R_{\text{virial}} < 3h_{70}^{-1}$ Mpc. For this paper, the virial radius for the Coma cluster is assumed to be $2h_{70}^{-1}$ Mpc based on the weak-lensing analysis of Kubo et al. (2007). Any reference to the cluster core in this paper implies a region at $\lesssim 0.2R_{\text{virial}}$ from the cluster centre. Throughout this paper, we will refer to the pair of clusters Coma and Abell 1367, along with the associated filament of galaxies, as the Coma supercluster.

2 DATA

The optical photometric and spectroscopic data acquired by the SDSS DR7 (Abazajian et al. 2009) are used to select the galaxies belonging to the Coma supercluster from the SDSS spectroscopic galaxy catalogue only, requiring the member galaxies to be within $170^\circ \leq R.A. \leq 200^\circ$ and $17^\circ \leq \text{Dec.} \leq 33^\circ$ on the sky, and with a radial velocity within 3000 km s$^{-1}$ of the mean redshift of the Coma supercluster. All our galaxies are brighter than the SDSS magnitude $r = 17.77$ (−($M^* + 4.7$) for the Coma cluster), which is the magnitude limit of the SDSS spectroscopic catalogue. In order to select the dwarf population by stellar mass, we define galaxies with $z \geq 15$($M^* + 2$) as ‘dwarfs’ throughout this work, since it is relatively extinction free compared to other SDSS bands. However, we note that for the sample presented here, the $r$ and $z$ bands are linearly correlated. This gives us a sample of 3050 dwarf galaxies, which is used in this paper.

The k+A galaxies, defined to have $>3$ Å of Hβ in absorption and $<2$ Å of Hα in emission, are taken from the catalogue compiled in Mahajan et al. (2010a). Hereafter, we consider all galaxies with EW (Hα) > 2 Å, where EW represents equivalent width, as star forming and any reference to galaxy colour in context of this work refers to the broad-band $(g - r)$ colour (see Section 3).

3 COLOUR AND ENVIRONMENT

In Fig. 1, we plot the radial dependence of $(g - r)$ for all dwarf ($r \leq 17.77$; $z > 15$) galaxies found in and around the Coma cluster. The mean colour of dwarfs changes from 0.3 around $3R_{\text{virial}}$ away from the centre to 0.7 in the core of the cluster. It is also interesting to note that even with dwarfs alone, the red sequence for the Coma cluster extends beyond the virial radius, suggesting that the potential well of the cluster effectively contributes to the evolution of all galaxies as far as the cluster periphery (see also Gavazzi et al. 2010).

The k+A galaxies in the vicinity of the Coma cluster span a wide range in $(g - r)$ colour, such that most of the blue k+A galaxies lie within $R_{\text{virial}}$. The blue colour of some k+A galaxies suggests that the star formation in these galaxies has been very rapidly quenched no longer than 500 Myr ago (also see Poggianti et al. 2004). In contrast, a Gyr should have elapsed since the termination of the last major episode of star formation in the red k+A galaxies, allowing for their observed $(g - r)$ colour. The k+A dwarfs show a relatively scattered distribution compared to red dwarfs. Assuming that some of these galaxies are seen in projection along the line of sight, it is fair to state that the k+A galaxies prefer intermediate-density regions found in the outer regions and vicinity of rich clusters and groups (Figs 1 and 2; also see fig. 12 of Mahajan et al. 2010a, for positions of k+A galaxies in the clusters), indicating a possible link between the processes contributing to the k+A phase in dwarf galaxies and the depth of the cluster potential.
Figure 2. Top panel: the distribution of red (red points) and k+A (green points) dwarf \((r \leq 17.77; z > 15)\) galaxies in the Coma supercluster \((cz = 6973 \pm 3000 \text{ km s}^{-1})\). The purple circles represent galaxy groups from the literature that lie in the same redshift slice and the dashed circles are centred on cluster centres with a radius of 3\(R_{\text{virial}}\). Bottom panel: the same for blue galaxies with \(\text{EW}(\text{H}\alpha) < 50 \text{ Å}\) and \(\text{EW}(\text{H}\delta) \leq 0 \text{ Å}\) (orange points), starbursts \([50 \leq \text{EW}(\text{H}\alpha) \leq 80 \text{ Å}; \text{blue points}]\) and extreme starbursts \([\text{EW}(\text{H}\alpha) > 80 \text{ Å}; \text{blue stars}]\); also see Fig. 3). While the blue dwarfs trace the entire supercluster, the red ones are abundant in the high-density regions only. The k+A dwarfs are mostly confined to the vicinity of the two clusters and occasionally the galaxy groups.

We use the \((g-r)-M_r\) colour–magnitude diagram to separate red and blue galaxies in the Coma supercluster, where the blue galaxies are defined to have \((g-r)\) colour one mean absolute deviation below the fitted red sequence. For consistency in this work, we fitted this red sequence using dwarf galaxies only. This red sequence on an average assigns \((g-r) \sim 0.64\) mag to a galaxy of \(M_r = -17\) mag. The location of the red and blue dwarf galaxies across the Coma supercluster is shown in Fig. 2. The k+A galaxies and galaxy groups found in the NASA/IPAC Extragalactic Data base (NED) (see Mahajan et al. 2010a, for the selection criteria) are shown explicitly. The red dwarf galaxies trace the rich structures – clusters, groups and the filament – suggesting a stronger star formation–density relation than their blue counterparts.

4 SPECTRAL DIAGNOSTICS

In the absence of dust, the EW of H\(\alpha\) is a good indicator of the current SFR of galaxies. On the other hand, intrinsic H\(\delta\) absorption is a characteristic feature of A-type stars, which have a lifetime of 1–1.5 Gyr. Hence, a galaxy that experienced a burst of star formation 1–2 Gyr ago is likely to show strong absorption in H\(\delta\). But star-forming H\(\alpha\) regions in galaxies with ongoing starburst can produce enough ionizing radiation to fill in the H\(\delta\) absorption line.

In Fig. 3, we show the distribution of dwarfs in the Coma supercluster in the EW(H\(\alpha\))–EW(H\(\delta\)) plane, segregated into four bins of \((g-r)\) colour. The four colour bins are such that both the redder bins contain galaxies belonging to the red sequence. As galaxies become redder towards the cluster core (Figs 1 and 2), the narrow ridge formed by blue galaxies having very strong H\(\alpha\) emission, but negligible H\(\delta\) absorption, vanishes. In dealing with the spectral features, it is important to check whether the two populations seen in this EW(H\(\alpha\))–EW(H\(\delta\)) plane result from measurement uncertainties. In order to do that, we split the galaxies in each panel into those that have measurement uncertainty according to the SDSS, \(<15\) per cent of the measured EW for both H\(\alpha\) and H\(\delta\) (the coloured points in Fig. 3), and those that do not have (grey points in Fig. 3). As
expected, as the emission features become weak for the passively evolving red dwarfs, more galaxies inherit the uncertain zone.

However, among the blue, star-forming class, there exist at least two subpopulations, one that of the starburst dwarfs, which line up in a narrow ridge on the right-hand side of the EW(\text{H}_\alpha)–EW(\text{H}\delta) plane, and the other of normal star-forming and post-starburst galaxies that have significant absorption in \text{H}\delta. The latter class of blue dwarfs overlap with the red ones, showing relatively low EW(\text{H}_\alpha) and some absorption in \text{H}\delta. Although most of these galaxies have continuous star formation histories with a low SFR, a subpopulation might have been quenched recently (\lesssim 1 Gyr old; Poggianti et al. 2004) as they are assembled into clusters via the large-scale structure (see e.g. Mahajan, Raychaudhury & Pimbblet, in preparation), thus terminating the starburst. From Figs 1 and 2, it is also evident that although most of the blue dwarfs within \Delta_\text{final} of the cluster centres have low \text{H}_\alpha emission (<50 Å), such galaxies are found elsewhere in the supercluster as well.

The red dwarfs showing \text{H}\delta absorption similar to the blue galaxies could be (i) dominated by metal-rich stellar populations (Smith et al. 2008; Mahajan & Raychaudhury 2009); (ii) transformed large spiral galaxies, whose discs have been removed after they fell into the cluster (e.g. Abadi, Moore & Bower 1999; Barazza et al. 2009), due to the impact of environmental mechanisms, such as ram-pressure stripping (Gunn & Gott 1972); or (iii) star-forming dwarf galaxies in the early phases of transformation (Lin & Faber 1983; Boselli et al. 2008, and references therein). We discuss these possibilities further in Section 5.

In the Coma cluster, most (~71 per cent) of the dwarf galaxies are red (Fig. 1) and show no \text{H}_\alpha emission (Fig. 3). The fraction of non-emission line dwarfs is only ~25 per cent in the neighbouring Abell 1367 cluster. Given that a significant fraction of blue galaxies with more than 3 Å of absorption in \text{H}\delta also have <20 Å of emission in \text{H}\alpha (Fig. 3), it is likely that star formation in some of them was abruptly quenched.

5 DISCUSSION

In this work, we attempt to understand the origin of k+A galaxies and the possible evolutionary link between this transitional population and the red dwarfs found abundantly in the Coma cluster (e.g. Jenkins et al. 2007; Chiboucas et al. 2010). We use the publicly available SDSS DR7 data for the entire supercluster, with a view to studying the influence of large-scale structure, if any, on the evolution of the k+A galaxies in the low-redshift Universe. In agreement with other studies of cluster dwarfs in the nearby Universe (e.g. Poggianti et al. 2004; Boselli et al. 2008), we find that the k+A galaxies prefer the intermediate-density regions in the vicinity of rich structures. General studies of k+A galaxies at z = 0 also reveal that they preferentially avoid very low and high density regions (Balogh et al. 2005; Goto 2005).

If star formation in a galaxy is truncated by some mechanisms affecting the halo gas, star formation is quenched on long time-scales of ~1 Gyr (e.g. Kodama & Bower 2001; Kawata & Mulchaey 2008). However, if the star formation is suddenly quenched, for instance, when a galaxy encounters the cluster environment and is stripped not only of the reservoir of gas, but also of the supply for ongoing star formation, then the SFR declines on much shorter time-scales of ~100–150 Myr. Thus, one is more likely to observe the transient populations, such as the blue passive galaxies (e.g. Mahajan & Raychaudhury 2009) and k+A galaxies in the latter scenario. This is also consistent with the idea that an infalling galaxy can lose most of its gas in a starburst or violent encounters with fellow infalling galaxies on the cluster periphery (Mahajan et al., in preparation and references therein) and subsequently evolve in a passive fashion as it settles into the cluster core, on a time-scale equivalent to a few times the cluster crossing time (~1 Gyr).

For the dwarf galaxies falling into clusters and groups in the Coma supercluster, the velocity field varies significantly depending upon the depth of the potential well they are approaching. Hence, it is likely that the galaxies falling into deeper potentials undergo a burst of star formation in which they either exhaust all the gas content and/or lose it through interactions with the intracluster medium, thus experiencing a sudden and rapid cessation in star formation (e.g. Tzanavaris et al. 2010, also see Fig. 5). On the other hand, galaxies falling into relatively shallower potentials are likely to suffer slow quenching. This explains the presence of dwarf k+A galaxies mostly in the vicinity of the two rich clusters, Coma and Abell 1367, and occasionally in galaxy groups embedded in the filament crossing them (Fig. 2).

In the Coma supercluster, we find that around 86 per cent (78 per cent) of all the k+A dwarfs are found within 10 (5) h_70^{-1} Mpc of the centre of the clusters, suggesting a close link between the transitional k+A population and the cluster environment. Consistent with previous results (Poggianti et al. 2004), we find that most of the blue k+A dwarfs in the vicinity of the Coma cluster are found within its virial radius. The blue colour of some k+A galaxies suggests that the star formation in these galaxies has been quenched rapidly within the last 500 Myr. These observations are similar to those made for the comparable Virgo cluster. Boselli et al. (2008) studied the evolution of dwarf (L_\text{K} < 10^6 M_\odot) galaxies in Virgo by comparing their ultraviolet to radio spectral energy distributions to multizone chemospectrophotometric models. Their results suggest

Figure 4. The distribution of the red (red dotted curve), blue (blue dashed curve) and k+A (green solid curve) galaxies as a function of the cluster-centric radius from the centre of the Coma cluster. 525, 157 and 67 galaxies contribute to each of the three curves, respectively. The thin lines corresponding to each distribution represent the ±1σ scatter, assuming binomial statistics. All curves are individually normalized to unity.

that not only is the star formation in the dwarf galaxies entering the Virgo cluster quenched on short (~150 Myr) time-scales, but most of the luminous late-type spirals might also be transformed to relatively massive dE galaxies in a similar fashion.

In Fig. 4, we find evidence to support a similar scenario in the Coma cluster. While the fraction of red dwarfs steadily increases from $4h_{70}^{-1}\text{Mpc}$ to the centre of the cluster, the population of blue dwarfs declines steadily within the virial radius. The distribution of k+A dwarf galaxies follows the red dwarfs. Since the k+A phase is relatively short lived (~0.5 Gyr; Balogh et al. 2005) in a galaxy’s lifetime, the observation of even a small fraction of such a transitional population suggests that a much larger proportion of all galaxies in the region may have passed through this stage.

Stellar population synthesis models suggest that galaxies with k+A spectral features (strong Balmer absorption and lack of emission) are best modelled as a post-starburst (Dressler & Gunn 1992; Poggianti et al. 1999, and references therein), that is, star formation is completely ceased following a burst. Studies of large-scale inter-cluster filaments provide statistical evidence to show that galaxies infalling into clusters are likely to undergo a starburst on the outskirts of clusters, before they are assimilated in their cores (see e.g. Porter et al. 2008; Mahajan et al., in preparation and references therein). These results imply that bursts of star formation in galaxies falling into clusters are inevitable consequences of the hierarchical assembly of structures. This is mainly dependent on two factors: (i) the gas content of the infalling galaxies; and (ii) the velocity field around the cluster (e.g. Mahajan, Mamon & Raychaudhury 2010b). This scenario is further supported by the SDSS-based study of k+A galaxies by Balogh et al. (2005), who find that the $(u-g)$, $(r-K)$ colours and the Hδ $\text{EW}$ of k+A galaxies are consistent with models where >5 per cent of the stellar mass of galaxies is formed in a recent starburst.

We find that 7.8 per cent of all dwarf galaxies within 3$R_{\text{virial}}$ of the Coma cluster are k+A galaxies, while in the relatively smaller Abell 1367, this fraction declines to 4.1 per cent within the same aperture. Furthermore, excluding the clusters, the fraction of k+A galaxies in the rest of the supercluster (Fig, 2) is only 1.4 per cent. The wide range of ages (~2–10 Gyr) and metallicities ($-1 \lesssim [\text{Fe/H}] \lesssim 0.0$) in the Coma cluster dwarfs suggests non-unique evolutionary histories for these galaxies (Lisker et al. 2007; Smith et al. 2008, and references therein). While some of the oldest red dwarfs, confined to the cluster core, may belong to the primordial

Figure 5. Typical SDSS spectra of a red (left-hand top panel), k+A (left-hand middle panel) and blue star-forming (left-hand bottom panel) dwarf galaxy in Coma, and their respective images (right-hand panels). All images are obtained in colour from the SDSS website. In this paper, we suggest that in the Coma supercluster, transformation of infalling star-forming dwarfs into passive ones occurs via a k+A phase, whereas the dwarf galaxies falling into relatively shallow potential wells of galaxy groups embedded elsewhere in the supercluster are likely to suffer slow quenching.
cluster population (Smith et al. 2009), others could have transformed from luminous late-type spirals, after their infall into the cluster (Fig. 5; also see Boselli et al. 2008; Barazza et al. 2009). The surface brightness profiles of dwarf (−18 ≤ Mp −16) galaxies in the Coma cluster also show that while the galaxies fitted with a single Sérsic profile (dE galaxies) could come from star-forming dwarfs, the dwarf lenticulars (fitted with Sérsic + exponential profile) are evolved spirals that were harassed during infall (Aguerri et al. 2005, also see Porter et al. 2008).

Figs 2 and 3 provide further clues to the evolution path adopted by dwarfs. While some blue galaxies show ongoing starburst (right-hand ridge in Fig. 3), star formation in others, especially those falling into clusters, must be suddenly quenched (Figs 2 and 4). On the other hand, the red galaxies trace the high-density regions, suggesting a relatively stronger star formation–density relation throughout the supercluster (Figs 1 and 2).

The range of values of various relevant measured parameters, explored in this paper for the dwarf galaxies in the Coma supercluster, do not allow us to subdivide our sample into galaxies with widely different evolutionary histories. Instead, by considering all dwarfs in Coma as a single ensemble, we have been able to provide some insight into the complex mix of star formation histories among this vulnerable population. It is interesting to note that contrary to the results presented in this paper, Yan et al. (2009) find that the giant k+A galaxies (0.1 < z < 0.8) show an environmental dependence similar to that of blue galaxies. In a study of 0.05–0.5L∗ galaxies in a cluster at z = 0.54, De Lucia et al. (2009) found only six post-starburst galaxies amongst the spectroscopic cluster members, thus suggesting that the transformation of star-forming infalling galaxies to the faint red ones found in the low-redshift clusters must have occurred primarily through physical processes that do not lead to a post-starburst phase. In order to establish and understand the mass dependence in the occurrence and nature of k+A galaxies, a homogeneous analysis of the spectroscopic properties of galaxies spanning a wide range of M∗ environments and different epochs is required. We intend to return to this in future.

6 CONCLUSIONS

By using the SDSS DR7 data from the spectroscopic galaxy catalogue for the dwarf (r ≤ 17.77; z > 15) galaxies in the Coma supercluster (z = 0.023), we have concluded the following:

(i) The mean (g − r) colour of dwarf galaxies in and around the Coma cluster increases from 0.3 at ∼3Rvirial to 0.7 in the core.

(ii) In the Coma supercluster, the k+A dwarf galaxies are mostly confined to the cluster infall regions, and occasionally galaxy groups, suggesting that most of the dwarf galaxies falling into the Coma and Abell 1367 clusters are likely to experience sudden quenching of star formation and hence are observable in the k+A phase. On the contrary, dwarfs falling into galaxy groups embedded in the filament are likely to suffer slow truncation.

(iii) The blue colour of some k+A dwarfs in the Coma cluster, lying within its virial radius, suggests that the star formation in these galaxies was quenched rapidly within the last 500 Myr. In contrast, the last major episode of star formation in the red k+A galaxies should have ceased on a time-scale of ∼1 Gyr.

(iv) Assuming the red dwarf galaxies to be passively evolving, they show a stronger star formation–density relation relative to their bluer counterparts.

(v) A significant fraction of all red galaxies in the Coma supercluster show some absorption in Hα (0–3 Å), suggesting that star formation in them could have been quenched within the last Gyr.

(vi) The populations of k+A and red dwarfs increases towards the cluster core in Coma from almost twice the virial boundary, while that of the blue ones decreases steadily. The k+A galaxy distribution is flatter relative to red dwarfs and they are not as concentrated in the core of the cluster as the red dwarfs, suggesting that the k+A galaxies preferentially avoid very dense and underdense regions in equal measures.

ACKNOWLEDGMENTS

This research has made use of the SAO/NASA Astrophysics Data System and the NED. Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the US Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society and the Higher Education Funding Council for England.
