ABSTRACT

Context. Physically unassociated background or foreground objects seen towards submillimetre sources are potential contaminants of both the studies of young stellar objects embedded in Galactic dust clumps and multiwavelength counterparts of submillimetre galaxies (SMGs).

Aims. We aim to search for and characterise the properties of a potential extragalactic object seen in projection towards a Galactic dust clump.

Methods. We employed the near-infrared (3.4 µm and 4.6 µm) and mid-infrared (12 µm and 22 µm) data from the Wide-field Infrared Survey Explorer (WISE) and the submillimetre data from the Planck satellite.

Results. We uncovered a source, namely the WISE source J044232.92+322734.9 (hereafter J044232.92), which is detected in the W1–W3 bands of WISE, but undetected at 22 µm (W4), and whose WISE infrared (IR) colours suggest that it is a star-forming galaxy (SFG). This source is seen in projection towards the Planck-detected dust clump PGCC G169.20-8.96, which likely belongs to the Taurus-Auriga cloud complex, at a distance of 140 pc. We used the MAGPHYS+photo-z spectral energy distribution (SED) code to derive the photometric redshift and physical properties of J044232.92. The redshift was derived to be $z_{\text{phot}} = 1.132^{+0.280}_{-0.165}$, while, for example, the stellar mass, IR (8–1000 µm) luminosity, and star formation rate were derived to be $M_*=4.6^{+155}_{-121} M_\odot$, $L_\text{IR} = 2.8^{+4.7}_{-2.8} \times 10^{10} L_\odot$, and SFR $= 191^{+580}_{-146} M_\odot$ yr$^{-1}$ (or $281^{+580}_{-150} M_\odot$ yr$^{-1}$ when estimated from the IR luminosity). The derived value of $L_\text{IR}$ suggests that J044232.92 could be an ultraluminous IR galaxy, and we found that it is consistent with a main sequence SFG at a redshift of 1.132.

Conclusions. The estimated physical properties of J044232.92 are comparable to those of SMGs, except that the derived stellar mass of J044232.92 appears somewhat higher (by a factor of 4–5) than the average stellar masses of SMGs. However, the stellar mass difference could just reflect the poorly sampled SED in the ultraviolet, optical, and near-IR regimes. Indeed, the SED of J044232.92 could not be well constrained using the currently available data (WISE only), and hence the derived redshift of the source and its physical properties should be taken as preliminary estimates. Further observations, in particular high-resolution (sub-)millimetre and radio continuum imaging, are needed to better constrain the redshift and physical properties of J044232.92 and to see if the source really is a galaxy seen through a Galactic dust clump, in particular an SMG population member at $z \sim 1.1$.

Key words. ISM: clouds – galaxies: active – ISM: individual objects: PGCC G169.20-8.96 – infrared: galaxies – submillimeter: ISM – galaxies: individual: WISE J044232.92+322734.9

1. Introduction

Identifying the multiwavelength counterparts of an astrophysical object is an important step towards understanding the physical properties of the source. For example, if a Galactic molecular cloud core is found to be associated with a mid-infrared (IR) point source, the core is likely to harbour an embedded protostar (as opposed to a starless or prestellar core; see e.g. Dunham et al. 2014 for a review). A corresponding example in extragalactic astronomy is the identification of multiwavelength counterparts of galaxies. For example, a reliable identification of the observed-frame optical, near-IR, and mid-IR counterparts of the most intense dusty star-forming galaxies (SFGs) in the observable Universe, the so-called submillimetre galaxies (SMGs; see Casey et al. 2014; Hodge & da Cunha 2020 for reviews), is a prerequisite to determine their photometric redshifts and physical properties through spectral energy distribution (SED) analysis (e.g. Miettinen et al. 2017; Brisbin et al. 2017).

A Galactic molecular cloud clump or core can have a background star (or stars) seen through the object’s dusty medium (e.g. Alves et al. 2001). A similar chance alignment can also happen with foreground stars, but the stars are not reddened as in the case of background stars. In the case of SMGs, a background or a foreground galaxy can be incorrectly interpreted to be physically associated with the observed-frame submillimetre dust emission, especially if the projected angular separation between the two is on a sub-arcsecond scale. Such source contamination will then lead to a wrong redshift of the SMG (either too high or too low) and correspondingly incorrect physical properties, such as the stellar mass content and luminosity.

In this paper, we present a potential case where an extragalactic object, namely an SFG, is projectively seen towards a Galactic molecular cloud clump. The target sources and data are described in Sect. 2, while the analysis and results are described in Sect. 3. The results are discussed in Sects. 4 and 5 summarises our results and main conclusions.
Throughout this paper, we assume a ΛCDM (Lambda Cold Dark Matter) cosmology with the dark energy density Ω_0 = 0.7 and total matter density Ω_m = 0.3, while the Hubble constant is set to H_0 = 70 km s^{-1} Mpc^{-1}. We report the magnitudes in the Vega system, and notations such as [3.4] refer to the Vega magnitude at a wavelength of 3.4 μm. We adopt a Chabrier (2003) Galactic-disc initial mass function (IMF). We define the spectral index, as S_ν ∝ ν^n, where S_ν is the flux density at frequency ν.

2. Target sources and observations

To search for a potential example case where an external galaxy is seen through a Galactic dust clump, we started from the whole-sky observations made with the Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010) at 3.4, 4.6, 12, and 22 μm. As discussed by Koenig et al. (2012), SFGs exhibit an elevation in the emission from polycyclic aromatic hydrocarbons, and this phenomenon can be seen in the WISE [4.6]–[12] IR colour of the galaxy. On the basis of the earlier Spitzer IR colour criteria (e.g. Gutermuth et al. 2008; Koenig et al. 2012) determined the following WISE IR colour criteria to identify SFGs (see Appendix A.1 therein):

\[
\begin{align*}
[3.4] - [4.6] &< 0.46 \times ([4.6] - [12] - 1.7) \\
[3.4] - [4.6] &> -0.06 \times ([4.6] - [12] - 4.67) \\
[3.4] - [4.6] &< -1.0 \times ([4.6] - [12] - 5.1) \\
[3.4] - [4.6] &> 0.48 \times ([4.6] - [12] - 4.1) \\
[4.6] &> 12 \\
[4.6] - [12] &> 2.3.
\end{align*}
\] (1)

We note that there are also WISE IR colour criteria to identify potential active galactic nuclei (AGN; Koenig et al. 2012; Appendix A.1 therein), but AGN are not considered in the present study.

We searched for sources from the AllWISE catalogue\(^1\) that fulfil all the criteria in Eq. (1). We note that the source needs to be detected in the WISE bands W1–W3 (3.6, 4.6, and 12 μm) so that the inequalities in Eq. (1) are well defined. To avoid very red sources that are strong in the 22 μm (W4) band of WISE, for example the young stellar objects (YSOs) embedded in Galactic molecular clouds, the search was, somewhat arbitrarily, limited to sources with [22] > 5. For comparison, about 79% of the known YSOs in the Taurus-Auriga region in the Rebull et al. (2011) catalogue have 22 μm magnitudes of [22] ≤ 5. As an additional constraint, the WISE source was required to be unaffected by known artefacts, that is the ccf flag in the AllWISE catalogue was set to 0000.

To search for potential foreground dust clumps, we employed the Planck\(^2\) Catalogue of Galactic Cold Clumps (PGCC; Planck Collaboration XXVIII 2016). The PGCC catalogue contains 13 188 Galactic sources spread across the whole sky (13 242 sources in total, of which 54 are in the Small and Large Magellanic Clouds), including those at high Galactic latitudes, and hence it is well suited for our purpose because there is a higher probability of finding a background extragalactic source at high Galactic latitudes than close to the Galactic plane. For example, 27% of the PGCC sources lie at Galactic latitudes between b = 5° and b = 40°, and 31% are between b = −5° and b = −40° (cf. Fig. 3 in Planck Collaboration XXVIII 2016). Another important advantage of PGCC is that about 42% of its sources (5574) have reliable distance estimates available. This allowed us to confirm that the dust clump belongs to the Galaxy, and a known distance also allows the determination of the physical properties of the clump, such as its projected physical size and mass, which are also available in the PGCC catalogue. The right ascension distribution of the sources in the PGCC catalogue is double-peaked so that 44% of the sources lie at α_{2000.0} = 40°−150° and 40% of the sources are at α_{2000.0} = 230°−360°. In the present study, we focussed on the former right ascension interval.

It should be noted that the AllWISE catalogue is extremely large and contains data for almost 7.5 × 10\(^8\) sources, and the full catalogue file size is 1.225 terabytes. For this reason, our search made use of only a fraction of the AllWISE catalogue. In practice, our source search procedure was executed as follows. We first downloaded a sample of million sources from the AllWISE catalogue (1.3 per mille of the full catalogue) that have the magnitudes [4.6] > 12 (the fifth inequality in Eq. (1)) and [22] > 5, are free of known artefacts, and lie at α_{2000.0} = 40°−150°. After applying the remaining colour criteria in Eq. (1), we were left with 318 958 WISE sources. The latter catalogue was cross-matched with the PGCC catalogue using a search radius of 10′, which is a somewhat arbitrary choice and only 3.5%–3.9% of the Planck beam size (full width at half maximum, FWHM) at 350 μm–850 μm (see Table 1 in Planck Collaboration XXVIII 2016). Only one case was found, namely WISE J044232.92+322734.9 (hereafter J044232.92), which is seen towards the Planck source PGCC G169.20-8.96 (hereafter G169.20-8.96), and where the projected angular separation between the two is 4′/15.

In Fig. 1, we show a Planck cutout image at 545 GHz (550 μm) towards G169.20-8.96. The WISE images at all four

\(^2\) Planck (http://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states (in particular the lead countries France and Italy), with contributions from NASA (USA) and telescope reflectors provided by a collaboration between ESA and a scientific consortium led and funded by Denmark.
IR wavelengths (W1–W4) towards J044232.92 are shown in Fig. 2. The WISE photometric data of J044232.92 are given in Table 1, and selected properties of G169.20-8.96 are summarised in Table 2. We note that the clump masses and densities reported in the PGCC catalogue were derived assuming a dust-to-gas mass ratio of $R_{\text{d}} = 1/100$ and a mean molecular weight of $\mu = 2.33$ (Planck Collaboration XXVIII 2016). However, the aforementioned value of $R_{\text{d}}$ refers to the canonical dust-to-hydrogen mass ratio, and the masses and densities listed in Table 2 were scaled upwards by using a dust-to-gas mass ratio of $R_{\text{d}} = 1/141$, which follows from the assumption that the chemical composition of the clump is similar to the solar mixture, where the hydrogen mass percentage is $X = 71\%$ and those of helium and metals are $Y = 27\%$ and $Z = 2\%$ (in which case the ratio of total gas mass (hydrogen, helium, and metals) to hydrogen gas mass is $(X + Y + Z)/X = 1.41$; e.g. Anders & Grevesse 1989; Kauffmann et al. 2008). The aforementioned mean molecular weight refers to that per free particle, $\mu_p$, and is valid for a [He]/[H] ratio of 0.1 with no metals. However, we scaled the densities downward by using a mean molecular weight per H$_2$ molecule, which in our case is $\mu_{\text{H}_2} = 2/X = 2.82$ (Kauffmann et al. 2008, Appendix A.1 therein).

### Table 1. Coordinates and photometric data of WISE J044232.92+322734.9.

| $\alpha_{2000.0}$ [h:m:s] | $\delta_{2000.0}$ ['":"'] | W1(3.4\(\mu\)m) | W2(4.6\(\mu\)m) | W3(12\(\mu\)m) | W4(22\(\mu\)m) |
|--------------------------|------------------------|-----------------|-----------------|-----------------|-----------------|
| 04 42 32.92 +32 27 34.9  | 15.601 ± 0.051         | 15.108 ± 0.097  | 12.017 ± 0.345  | >8.254          |
| ...                      | 0.176 ± 0.008 mJy      | 0.155\(^{+0.1014}_{-0.011}\) mJy | 0.453\(^{+0.170}_{-0.123}\) mJy | <3.723 mJy |

Notes. The WISE magnitudes given in the first row were taken from the AllWISE catalogue (the total in-band brightness). The W4 magnitude lower limit refers to the 95% confidence brightness limit. The WISE flux densities listed in the second row were computed from the magnitude values by applying the colour corrections under the assumption of a S\(\nu\) \(\propto\) \(\nu^{-2}\) power-law spectrum. Moreover, an additional W4 correction was applied to calculate the 22\(\mu\)m flux density upper limit (see Cutri et al. 2012).

### Table 2. Properties of the dust clump PGCC G169.20-8.96.

| $\alpha_{2000.0}$ [h:m:s] | $\delta_{2000.0}$ ['":"'] | $d$ [pc] | $D$ [pc] | $T_{\text{dust}}$ [K] | $\beta$ | $M$ [$M_\odot$] | $n(\text{H}_2)$ [$10^3$ cm$^{-3}$] | $N(\text{H}_2)$ [$10^{21}$ cm$^{-2}$] |
|--------------------------|------------------------|---------|---------|-----------------|------|--------------|----------------|----------------|
| 04 42 33.22 +32 27 36.80 | 140 ± 0.15             | 0.38 ± 0.04 | 12.2 ± 2.0 | 1.98 ± 0.60     | 3.4 ± 2.0 | 1.7 ± 1.0 | 1.3 ± 0.7 |

Notes. The coordinates refer to the PGCC catalogue position of G169.20-8.96. The other parameters in the table are the source distance ($d$), FWHM diameter of the clump ($D$), dust temperature derived from a modified blackbody fit to the clump SED ($T_{\text{dust}}$), dust emissivity index corresponding to the SED fit ($\beta$), total mass of the clump ($M$), average H$_2$ number density of the clump ($n(\text{H}_2)$), and H$_2$ column density of the clump. All the parameters were taken from the PGCC catalogue, but the mass and density values were scaled by using the present assumptions about the dust-to-gas mass ratio and mean molecular weight (see Sect. 2 for details).

3 Spectral energy distribution modelling of WISE J044232.92+322734.9

If J044232.92 is an external SFG, an obvious question is what is the redshift of the source. To determine the photometric redshift of J044232.92, we constructed its SED from the WISE photometric data shown in Table 1, and fit the SED using an extension of the multiwavelength spectral modelling code MAGPHYS (da Cunha et al. 2008, 2015) called MAGPHYS+photo-z (Battisti et al. 2019). Besides the photometric redshift, MAGPHYS+photo-z allows a simultaneous determination of the physical properties of the galaxy, such as its stellar and dust mass contents and the star formation rate (SFR). The uncertainties in the derived physical properties are propagated from the redshift uncertainty. The MAGPHYS SED modelling is based on the assumption of a global energy balance between stellar and dust emissions, that is the ultraviolet (UV) and optical photons emitted by young stars are absorbed (and scattered) by dust grains in star-forming regions and more diffuse parts of the

3 All versions of MAGPHYS are publicly available, and can be retrieved at http://www.iap.fr/magphys/magphys/MAGPHYS.html
galactic interstellar medium, and the heated dust subsequently reradiates the absorbed energy in the IR. The dust heating is assumed to be predominantly caused by star formation activity, while the potential contribution from an AGN is not taken into account.

The best-fit SED of J044232.92 is shown in Fig. 3 and the derived photo-z and physical properties of J044232.92 are listed in Table 3. The corresponding likelihood distributions are shown in Fig. 4. Following da Cunha et al. (2015), Miettinen et al. (2017), Battisti et al. (2019), the flux density upper limit (the observed-frame 22 µm data point) was taken into account in the SED fitting by setting the nominal value to zero, and using the upper limit value as the flux density uncertainty. As can be seen in Fig. 3, the best-fit model is consistent with this upper limit value. We note that owing to the small number of data points in our SED (only three detections plus one left-censored data point), MAGPHYS output a χ² goodness-of-fit value (see Eqs. (32) and (33) in da Cunha et al. 2008) of zero for the best-fit model plotted in Fig. 3.

For comparison with the SED of J044232.92, in Fig. 3 we also plot the SED of G169.20-8.96, which is constructed from the Planck flux densities at 353, 545, and 857 GHz (i.e. at about 850, 550, and 350 µm), $S_{850}\,\mu m = 15.5\pm2.3\,Jy$, $S_{550}\,\mu m = 49.1\pm7.0\,Jy$, and $S_{350}\,\mu m = 124.7\pm21.5\,Jy$), and the 100 µm flux density of $S_{100}\,\mu m = 14.1\pm9.2\,Jy$ measured with the Infrared Astronomical Satellite (IRAS; Neugebauer et al. 1984), which is also reported in the PGCC catalogue. The latter data were fitted with a single-temperature modified blackbody model (e.g. Casey 2012; Bianchi 2013), where we assumed that the dust emission is optically thin ($\tau \ll 1$). It was also assumed that the frequency-dependent dust opacity has the same form that is used by the Planck Collaboration XXXVIII (2016), that is the Beckwith et al. (1990) description $\kappa_\nu = 0.1\times(\nu/1\,\mathrm{THz})^\beta\,\mathrm{cm^2\,g^{-1}}$, where $\beta$ was fixed at 1.98 (see Table 2).

Besides the SFR derived from the MAGPHYS+photo-z SED modelling, the total IR luminosity in the rest-frame wavelength range of $\lambda_{\text{rest}} = 8\,\mu m$–1 mm can be used to derive another estimate of the SFR. The standard SFR($L_{\text{IR}}$) relationship from Kennicutt (1998; here scaled to a Chabrier 2003 IMF by dividing the original relationship by a factor of 1.7) is given by

$$\text{SFR}[M_\odot\,\text{yr}^{-1}] = 10^{-10} \times L_{\text{IR}}[L_\odot].$$

(2)

Kennicutt (1998) relationship yields an SFR that refers to a stellar mass range of 0.1–100 M_\odot and which is averaged over the past 100 Myr (i.e. the same timescale to which our MAGPHYS based SFR refers). The Kennicutt (1998) calibration is based on the assumptions of solar metallicity and an optically thick star-forming cloud, and hence in the above comparison we used a similarly defined SFR, which is $184 \, M_\odot\,\text{yr}^{-1}$ for J044232.92. Also, the aforementioned SFR comparison with the Miettinen et al. (2017) value is based on the values derived from the Kennicutt (1998) relationship (Eq. (2)). Because the derived photo-z of J044232.92, $z_{\text{phot}}=1.132\pm0.209$, is lower than the typical redshifts of the SMGs in the samples of da Cunha et al. (2015; $z_{\text{median}}=2.3$) and Miettinen et al. (2017; $z_{\text{median}}=2.3$), the 4–5 times higher stellar mass of J044232.92 compared to the typical aforementioned SMGs might not be appropriate for J044232.92 unless the source really is such an SFG.

Fig. 3. Best-fit rest-frame SED of J044232.92. The red points represent the observed photometric data points, and the one with a downwards pointing arrow marks the $A_{850} = 22\,\mu m$ upper flux density limit, which is taken into account in the fit. The blue line is the best-fit MAGPHYS+photo-z model SED (Battisti et al. 2019). For comparison, the far-IR to submillimetre SED of G169.20-8.96 is shown with green points indicating the IRAS 100 µm and Planck photometric data points and the green dashed line representing a single-temperature modified blackbody fit to those data (see text for details).

4. Discussion

4.1. Nature of WISE J044232.92+322734.9

Owing to the small amount of data available for J044232.92, its SED is poorly constrained, and hence the physical properties of the source derived in Sect. 3 should be taken with caution. In particular, a reliable determination of the photo-z would require data at multiple different wavelengths in the observed-frame optical and near-IR bands, which are typically only available for extragalactic survey fields such as the Cosmic Evolution Survey (COSMOS; Scoville et al. 2007). Moreover, the MAGPHYS+photo-z templates are optimised for $z > 1$ SFGs (da Cunha et al. 2015; Battisti et al. 2019), which might not be appropriate for J044232.92 unless the source really is such an SFG.

da Cunha et al. (2015) and Miettinen et al. (2017) used the same high-z MAGPHYS model libraries as in the present study to derive the physical properties for their samples of SMGs. The stellar mass, dust luminosity, SFR, dust temperature, and dust mass derived for J044232.92 are 5.1, 0.8, 0.7, 0.9, and 1.0 times the nominal, full sample averages from da Cunha et al. (2015), and 4.2, 0.6, 0.4, 0.9, and 0.6 times the sample averages from Miettinen et al. (2017). We note that da Cunha et al. (2015) defined the SFR as the average over the past 10 Myr, and hence in the above comparison we used a similarly defined SFR, which is $184 \, M_\odot\,\text{yr}^{-1}$ for J044232.92. Also, the aforementioned SFR comparison with the Miettinen et al. (2017) value is based on the values derived from the Kennicutt (1998) relationship (Eq. (2)). Because the derived photo-z of J044232.92, $z_{\text{phot}}=1.132\pm0.209$, is lower than the typical redshifts of the SMGs in the samples of da Cunha et al. (2015; $z_{\text{median}}=2.3$) and Miettinen et al. (2017; $z_{\text{median}}=2.3$), the 4–5 times higher stellar mass of J044232.92 compared to the typical aforementioned SMGs might not be an indication that the galaxy is more evolved and has assembled a higher stellar mass content, but the stellar mass of J044232.92 could also be overestimated owing to the lack of data in the UV, optical, and near-IR regime. Otherwise the physical properties of J044232.92 appear to be comparable to those of SMGs. Also, the derived total IR luminosity of J044232.92, $L_{\text{IR}} = 2.8\pm5.1 \times 10^{12} \, L_\odot$, suggests that it is an ultraluminous IR galaxy (ULIRG; e.g. Sanders et al. 1988).

To test how J044232.92 compares with the main sequence (MS) of SFGs, we used the Speagle et al. (2014) MS, which is
Table 3. Results of MAGPHYS+photo-z SED modelling of J044232.92.

| Parameter          | Likelihood | Prior | Median | 68% CI |
|--------------------|------------|-------|--------|--------|
| $z_{\text{phot}}$ | 1.132$^{+0.0280}_{-0.165}$ | 11.66$^{+0.31}_{-0.33}$ | 12.46$^{+0.48}_{-0.35}$ | 91$^{+380}_{-146}$ |
| $\log(M_{\star}/\odot)$ | 38.8$^{+1.10}_{-1.71}$ | 8.74$^{+0.72}_{-0.63}$ |
| $\log(L_{\text{dust}}/L_{\odot})$ | | | | |
| SFR ($\odot$ yr$^{-1}$) | | | | |
| $T_{\text{dust}}$ [K] | | | | |
| $\log(M_{\text{dust}}/M_{\odot})$ | | | | |

Notes. The parameters given in the table are the photometric redshift ($z_{\text{phot}}$), stellar mass ($M_{\star}$), dust luminosity in the rest-frame wavelength range of $\lambda_{\text{dust}} = 3 \mu$m–1 mm ($L_{\text{dust}}$), SFR averaged over the past 100 Myr, luminosity-weighted dust temperature ($T_{\text{dust}}$; see Eq. (8) in da Cunha et al. 2015), and dust mass ($M_{\text{dust}}$). The quoted uncertainties represent the 16th–84th percentile range of the likelihood distribution (68% confidence interval). \(^{(a)}\)The proportion of $L_{\text{dust}}$ that is emitted in the far-IR range of $\lambda_{\text{dust}} = 42.5–122.5 \mu$m is $f_{\text{IR}} = 0.895$, while that in the total-IR range of $\lambda_{\text{dust}} = 8 \mu$m–1 mm is $f_{\text{IR}} = 0.976$. \(^{(b)}\)An SFR calculated using the SFR($L_{\text{IR}}$) relationship of Kennicutt (1998) is 281$^{+56}_{-135}$ $M_{\odot}$ yr$^{-1}$ (see Eq. (2)).

Fig. 4. Likelihood distributions of redshift, stellar mass, dust luminosity, SFR, dust temperature, and dust mass. For parameters with priors, the prior distribution is shown by a green line. In each panel, the blue dashed line shows the median value of the parameter with the 16th–84th percentile range indicated by red dashed lines.

defined as

$$\log \left( \frac{\text{SFR}}{M_{\odot} \text{ yr}^{-1}} \right)_{\text{MS}} = (0.84 - 0.026 \times \tau_{\text{univ}}) \log \left( \frac{M_{\star}}{M_{\odot}} \right) - (6.51 - 0.11 \times \tau_{\text{univ}}),$$

where $\tau_{\text{univ}}$ is the age of the universe in Gyr ($\tau_{\text{univ}} = 5.259$ Gyr at the derived redshift of J044232.92). Using the nominal redshift, stellar mass, and SFR values derived with MAGPHYS+photo-z, we obtain a starburstiness parameter, that is the distance from the MS, of $\Delta_{\text{MS}} = \text{SFR}/\text{SFR}_{\text{MS}} = 1.03$. If using the SFR derived from Eq. (2), we obtained a value of $\Delta_{\text{MS}} = 1.51$. Both of these estimates of $\Delta_{\text{MS}}$ suggest that J044232.92 is a MS galaxy (see e.g. Miettinen et al. 2017 and references therein for different MS offset criteria; Sect. 4.1.1 therein).

4.2. Nature of PGCC G169.20-8.96

The coordinates and distance of G169.20-8.96 suggest that it is a member of the Taurus-Auriga molecular cloud complex at $d = 140$ pc (e.g. Kenyon et al. 1990; see also Güdel et al. 2007 and Kenyon et al. 2008 for reviews). Unfortunately, G169.20-8.96 lies outside the regions of panchromatic observations of Taurus (see e.g. Fig. 1 in Güdel et al. 2007), for example those in the optical with the MegaCam on the Canada-France-Hawaii Telescope (Boulade et al. 2003) and in the near to mid-IR with Spitzer (Werner et al. 2004). Moreover, G169.20-8.96 is outside of the Herschel (Pilbratt et al. 2010)\(^{4}\) fields observed as part of the Gould Belt Survey (GBS; André et al. 2010)\(^{5}\) as shown in Fig. 1 in Kirk et al. (2013).

The clump is cold, $T_{\text{dust}} = 12.2 \pm 2.0$ K, and has a mass of $3.4 \pm 2.0 M_{\odot}$ within a FWHM diameter of $0.38 \pm 0.04$ pc. Hence, G169.20-8.96 is a potential low-mass star-forming object. As seen in Fig. 1, G169.20-8.96 appears to be part of a system of three clumps that are blended in the Planck 550$\mu$m map. The beam-averaged H$_{2}$ column density of G169.20-8.96 is fairly low, $N(H_{2}) = (1.3 \pm 0.7) \times 10^{21}$ cm$^{-2}$, but higher resolution observations would undoubtedly reveal denser substructures within the clump.

Because the distance to G169.20-8.96 is only 140 pc, its angular size on the sky is large, 9:33 in FWHM diameter. This, together with its high absolute Galactic latitude of $|b| = 8^\circ96$ increase the probability for an extragalactic object seen along the line-of-sight towards the clump.

\(^{4}\) Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

4.3. Implications for studies of dust-obscured star-forming galaxies and Galactic molecular cloud clumps

Survey studies of high-redshift, dusty SFGs, especially the SMGs, often start by imaging an extragalactic field with a single-dish telescope at a (sub-)millimetre wavelength band (e.g. Scott et al. 2008; Weiß et al. 2009; Aretxaga et al. 2011). A common, subsequent step is to try to identify the multiwavelength counterparts of the identified (sub-)millimetre sources in order to derive their panchromatic SEDs and photometric redshifts. If, however, some of the originally uncovered (sub-)millimetre sources belong to the Galaxy, one could mistakenly interpret some galaxy to be an SMG although it would not be one. For example, the derivation of the photometric redshift of the counterpart galaxy could be based on the optical to near-IR data alone, and hence the presence of a Galactic contaminant could be missed.

As described above, a Galactic dust clump such as G169.20-8.96 in the Taurus-Auriga molecular cloud complex could erroneously be attributed to the dust emission of a dusty SFG, most notably an SMG. However, G169.20-8.96 is a much brighter submillimetre source than SMGs, and for example its 353 GHz or 850 μm flux density is reported to be $S_{850} = 15.5 \pm 2.3 Jy$ in the PGCC catalogue ( Sect. 3). For comparison, the brightest large APEX Bolometer Camera (LABOCA; Siringo et al. 2009) 870 μm selected SMG in the Extended Chandra Deep Field South (ECDF S) has an 870 μm flux density of 14.5 mJy ( Weiß et al. 2009), which is over 970 times lower than that of G169.20-8.96 ($S_{870} = 14.1 \pm 1.9 Jy$, which was calculated from $S_{850}$ assuming that $S_{v} \propto v^{-2.5}$ and using the $\beta$ value from Table 2). However, a direct comparison between the Planck and LABOCA flux densities is not totally fair because the Planck beam at 850 μm is over 14 times larger than that of LABOCA, and the spatial filtering by LABOCA makes it less sensitive to diffuse, large-scale emission seen by Planck. Nevertheless, a Galactic dust clump would be fairly easy to distinguish from a high-z SMG. A suspiciously bright (sub-)millimetre source could also be observed in spectral line emission (or absorption) to determine whether its radial velocity (and the corresponding kinematic distance) places it within the Galaxy and, hence, whether it is physically unrelated with the putative counterpart.

Moreover, although the Galactic latitude of G169.20-8.96 is low ($b = -8.96$), extragalactic survey fields have much higher absolute Galactic latitudes, $|b|$, where the occurrence of Galactic dust cores and clumps is lower than closer to the Galactic plane where molecular clouds are concentrated in (e.g. Dame et al. 2001). For example, $b = -54.44$ for the ECDF S (Giacconi et al. 2001, 2002) and $b = 42.12$ for COSMOS. Nevertheless, nearby dust clumps such as G169.20-8.96 might still be a concern.

On the other hand, an SFG, which appears as a mid-IR point source, could mistakenly be interpreted to be a YSO embedded in a Galactic molecular cloud clump or core seen in projection towards the SFG. In this case, the clump or core could be misclassified as protostellar although it could really be starless (and prestellar if it is also gravitationally bound). Such misclassification could then propagate to other, subsequent analyses, such as the duration of the starless phase of core evolution, which is sometimes derived from the relative numbers of starless and protostellar cores (the so-called statistical lifetime estimator; e.g. Jørgensen et al. 2007; Enoch et al. 2008; Evans et al. 2009).

5. Summary and conclusions

In the present paper, we have presented a potential example of a case where an external galaxy is seen in projection towards a dust clump in the Milky Way galaxy. The background extragalactic source is WISE J044232.92+322734.9, which was identified through IR observations with WISE, while dust clump in question is PGCC G169.20-8.96 that was uncovered by submillimetre observations with the Planck satellite. The dust clump lies at a distance of 140 pc, and is likely associated with the Taurus-Auriga complex.

We used the MAGPHYS photo-$z$ code to derive a photometric redshift estimate for J044232.92 and its basic physical properties. The photo-$z$ was derived to be $z_{\text{photo}} = 1.312 \pm 0.165$. While the stellar mass, $M_\star$ (8–1000 μm) luminosity, SFR, dust temperature, and dust mass were derived to be $M_\star = 4.6^{+0.7}_{-0.5} \times 10^{11} M_\odot$, $L_\text{IR} = 2.8^{+1.5}_{-1.1} \times 10^{12} L_\odot$, $91^{+280}_{-140} M_\odot \text{ yr}^{-1}$ ($281^{+560}_{-155} M_\odot \text{ yr}^{-1}$ from $L_{\text{IR}}$), $T_\text{dust} = 38.8^{+11.0}_{-7.1} K$, and $M_{\text{dust}} = 5.5^{+2.3}_{-1.4} \times 10^6 M_\odot$. The derived properties of J044232.92 suggest that it is a UHIRG that lies in the main sequence of SFGs. Its physical properties are also comparable to those of SMGs in the ECDF S and COSMOS fields. However, to our knowledge, J044232.92 has only been observed with WISE, and hence its SED could not be well constrained on the basis of the currently available data (detections in the WISE bands W1–W3 (3.4 μm–12 μm) and a non-detection in the W4 (22 μm) band). Therefore, the derived redshift and physical properties of J044232.92 should be considered as much more uncertain than the quoted formal uncertainties.

(Sub-)millimetre dust continuum and radio continuum imaging at high angular resolution would help to test the hypothesis that J044232.92 really is an SFG as suggested by its WISE IR colours, and whether it could belong to the SMG population at a redshift of about 1. High-resolution interferometric imaging would allow us to pinpoint the exact location and spatial extent of the potential dust-emitting region of J044232.92. For example, the present SED model prediction is that the observed-frame 850 μm flux density of J044232.92 is ~3 mJy, which would be only about 0.2 per mille of the Planck 850 μm flux density of G169.20-8.96. Follow-up observations of J044232.92 would be useful because they could reveal the presence of an SMG outside extragalactic survey fields and which could be a rare type of a projection of physically unassociated sources.
