**Introduction**

Human exhaled breath contains nitrogen (about 78%), oxygen (16%), carbon dioxide (4%-5%), hydrogen (5%), and water vapor. Besides, in the case of a healthy person, the exhaled air contains rather small concentrations of nitric oxide NO, ammonia NH₃, carbon monoxide CO, hydrogen dioxide H₂O₂ and sulphide H₂S as well as ethanol, acetone, etc. A remarkable increase in the concentration of last gases indicates the presence of various diseases in the patient. The metabolic excreted products diffuse into the inhaled air though the alveoli in the lungs and then the air is rejected. That is, a multi-component gas mixture formed, which accumulates first in the alveolus of the lungs. It is necessary to look for the cause of this either in incoming food (sources of volatile substances), or in internal organs, blood, blood vessels, sweat or urine. Today the medical doctor not only polls and examines the patient but also sends it to the lab-tests of blood, urine, perform an electrocardiogram, etc. But, for example, today’s periodic monitoring of glucose concentrations in the blood induces acute pain, risk of virus (e.g., hepatitis B) infection from needles, and other difficulties infrequent monitoring.

Intensive investigations of bio-safe small-sized semiconductor gas sensors for medical applications are carried out in recent years. Requirements for such biomarkers are their high sensitivity, selectivity, and stability to very low concentrations of gases, mainly exhaled by a living organism. The exhaled gases such as NOₓ, acetone, ethanol, NH₃, H₂S, and H₂O₂ can be used for sensors to diagnose various diseases. Non-invasive diagnostics of the patient, based on the analysis of exhaled air in a special device, allow only to make exhalation and after a few seconds-one minute to get the results of the analysis. The prospect of a non-invasive diagnosis is obvious - full safety from viral hepatitis, AIDS, and other infections.

Exhaled breath contains about 3500 volatile organic compounds (VOCs) that are the products of metabolism. But it is necessary to take into account that several important gases at some concentration in the air are immediately dangerous to life or health. According to the results of the study of volatile substances exhaled by a person, it is possible to judge the nature of nutrition - sufficiency of carbohydrates, excess fat and alcohol. By excess or lack of any chemical component in the spectrum of exhaled air, hereditary enzymopathy and the presence of various diseases can also be assumed. Due to the large surface of the lungs, volatile substances (ethanol, ammonia, acetone, and others) very quickly pass from the bloodstream to the external environment with exhaled air.

It is the mixture of various molecules secreted by a man that makes up the individual, unique smell of the patient. In a number of cases, this smell allows to immediately make the correct diagnosis. The sweet “liver odor” of explosives is due to a violation of the exchange of aromatic compounds and the accumulation of the product of the conversion of methionine - methyl mercaptan. This
smell of raw liver often haunts pancreatic cancer patients and may be one of the first symptoms of this ailment. The smell of ammonia in explosives is typical for kidney and uremia diseases, the “mouse smell” - for patients with hereditary phenylketonuria, the smell of syrup is in violation of the metabolism of fatty acids and the accumulation of keto acids and amino acids in the blood and urine, the smell of acetone - in patients with diabetes mellitus. A sharp specific smell from the mouth is a symptom of a number of diseases of the oral cavity and stomach ( stomatitis, periodontal disease, gastritis, peptic ulcer, and stomach cancer).

In cardiopulmonary insufficiency, unpleasant sour smell of under oxidized metabolic products associated with incomplete combustion of proteins, fats, and carbohydrates in the liver often comes from patients. An unusual persistent smell is a formidable symptom of a growing tumor of the anterior brain. It turned out that with a stroke with an unfavorable outcome, much less acetone is released in patients than in healthy people. At the same time, diabetics, who also fell into a coma, exhale tens and hundreds of times more acetone than healthy ones. The content of acetone and ethanol is significantly different from healthy individuals (in patients with diabetes mellitus, cardiovascular disease, in children with bronchial asthma, diathesis, in pregnant women with toxicities of the first half of pregnancy). We also note that it is possible to successfully detect using semiconductor sensors odorless substances, such as carbon monoxide (carbon monoxide) or carbon dioxide.

**Capabilities of Detection of Various Diseases**

Capabilities of detection of the various diseases using the analysis of the breath are discussed below. Data on the surveillance capabilities of diseases in the allocation of specific gases are collected below in Table 1. Naturally, assembled here material cannot be considered as exhaustive one. Note also that the analysis of the breath allows to detect (diagnose) cancer of stomach and ovaries, rheumatoid disease, acute myocardial infarction, gum disease, tooth decay, bacterial imbalance on the tongue, impacted wisdom teeth, dehydration, sleep apnea, gastric, stomach ulcers duodenal ulcers and other diseases can be carried out. The presence of heptane, xylene, octane, ethylbenzene, styrene, decane, toluene, benzene, and formaldehyde allow detecting lung cancer.

**Methods of the Study of the Compositions of Explosives**

From the middle of the 20th century to the present day, chromatography and mass spectrophotograph are among the most widely used analytical methods for studying explosives [1-5]. Many volatile metabolites were determined by these methods in explosives, many of which are used as markers of inflammation. Their specificity and sensitivity for the diagnosis of many diseases are determined. In addition to chromatography and mass spectrophotograph, radioimmune and enzyme-linked immunosorbent assays, spectrophotometry, fluorometric and chemiluminescent methods were proposed, the protein matrix and tumor necrosis factor are studied, etc. In medicine, when studying gas exchange, gas analyzers are used to measure the concentration of carbon dioxide, oxygen, and nitrogen in the inhaled and the exhaled gas mixture, to study blood gases and to measure the concentration of the indicator gas in the artificially created mixture when determining the number of respiration parameters (instruments for measuring gas concentration in a gas mixture). In recent years, ionic and proton mass spectroscopic methods and gas chromatography has been used. Of course, the possibility of physical-chemical studies of gas-phase are not limited to such analysis. Samples of internal abdominal gases can collect and examine from different sections of the bronchi with bronchoscopy, from the stomach with gastroscopy, from the colon with colonoscopy, from the bladder with cystoscopy, etc.

**Semiconductor Gas Sensors of Exhaled Breath**

It is important today we develop the individual metabolic profile of the patient. The equipment mentioned above is expensive and bulky, it is necessary to develop cheap, small-size and bio-safe measuring setups which can be used individually by a medical doctor and each patient elsewhere out of hospitals and specialized centers. Therefore, the use of semiconductor gas sensors for detecting the concentration of detectable gas (acetone in diabetes, for example) is widely discussed in the literature (see, for example, [6-21]).

Different metal oxide semiconductors for the manufacture of such sensors are proposed and investigated because they are not oxidized materials, have stable in time characteristics, and can work at its remarkable pre-heating. Determination of the concentration of chemical compounds in explosives using gas sensors will allow the diagnosis of the disease already in the early stages and will make it possible to control treatment. As was mentioned above, by the concentration of acetone and the amount of current passing through the semiconductor sensor, for example, one can judge the degree of diabetes, acute heart failure, lung cancer; hydrogen peroxide and nitric oxide - asthma and other pulmonary diseases, cancer of the digestive system; ammonia and hydrogen sulfide - hepatitis and cirrhosis; hydrogen and methane, a number of diseases of the digestive system, etc (Table 1). The current study of head, ovarian, bladder, prostate, kidney, gastric, as well as neck cancer, Crohn’s disease, ulcerative colitis, idiopathic and atypical Parkinson’s disease, multiple sclerosis, pulmonary hypertension, and other diseases is started now using semiconductor nanoarrays and artificial intelligence methods.

Table 1.

| Gases                  | Exhalation and Diagnostic Significance                                                                                                                                                                      |

Metal oxide semiconductors n-type SnO₂, ZnO, WO₃, TiO₂, MoO₃, In₂O₃, Fe₂O₃, and p-type CuO, NiO, Cr₂O₃, Mn3O4 are used during breath analysis [6,15,16]. Some interesting papers about sensors promising for breath analysis listed in Refs. [7,9-12,14]. Note that the disease diagnosis using exhaled breath is still in the nascent stage and needs further improvement for clinic applications.

**Detection of NO and NH₃ for the Diagnosis of Asthma and Renal Disease**

The most important biomarkers of diseases in human body are nitric oxide, ammonia, acetone, hydrogen dioxide and sulphide. Of course, a lot of information can be received from detection of other exhaled gases (Table 1). Villi-like WO₃ nanostructures show high gas responses (Rgas/Rair) ~30 to 0.2 ppm NO at 200°C [19]. It is shown also that WO₃ nanotubes exhibit high responses to 1 ppm NO. These results were obtained in highly humid (RH > 80%) atmospheres. BOSCH Healthcare Solutions announced a monitor that allowing measurements of fractional exhaled nitric oxide (FENO) for the diagnosis of asthma [22,23]. So, it is established that nitric oxide is an excellent biomarker of bronchial asthma.

The potential of WO₃ nanostructures for the diagnosis of asthma was demonstrated. This device consists of pretreatment components that precondition the exhaled gas and sensing components that measure FENO [24-27]. The initial stages of renal disease can be diagnosed by measuring NH₃ and H₂S vapors in exhaled breath [28-30]. End-stage renal disease (ESRD) requires time-consuming, expensive, and inconvenient hemodialysis, which significantly decreases the quality of life for patients. If the nephron function is completely lost, kidney transplantation needs to be...
After 2.5 minutes, exposure to 10-ppm °C [34,38] in the immune response, regulation of the functioning of the physiological functions. Satisfying the body's needs for nitric oxide that simple nitric oxide (NO) is involved in the regulation of many enzymes necessary for its production. It has now been proven that NO improves the situation. In clinical settings, NO gas has been approved by the US Federal Drug Administration for the treatment of hypertension, improved severe hypoxia and shortened the length of ventilatory support as compared to matched control patients with Severe Acute Respiratory Syndrome (SARS) Coronavirus. Nitric Oxide Gas as a drug greatly increased the survival rate of SARS-CoV-infected eukaryotic cells, suggesting direct antiviral effects of NO. In a subsequent in-vitro study, NO donors (e.g., S-nitroso-N-acetylpenicillamine) greatly increased the survival rate of SARS-CoV-infected eukaryotic cells, suggesting direct antiviral effects of NO. Coronavirus responsible for SARS-CoV shares most of the genome of COVID-19 is indicating potential effectiveness of inhaled NO therapy in these patients. Prolonged treatment with inhaled NO can lead to increased methemoglobin levels. Blood levels of methemoglobin will be monitored via a non-invasive CO-oximeter. It was also shown in Protokol [40] that inhaled nitric oxide gas (INO) has antiviral activity against other strains of coronavirus. The primary aim of this study is to determine whether inhaled NO improves the situation. In clinical settings, NO gas has been approved by the US Federal Drug Administration for the treatment of pulmonary hypertension of the newborn in the presence of hypoxic respiratory failure. In 2004, during SARS-CoV outbreak, it was reported the use of inhaled NO gas (iNO) in six patients with severe symptoms. Treatment with iNO reversed pulmonary hypertension, improved remarkably severe hypoxemia, and shortened the length of ventilatory support as compared to matched control patients with SARS-CoV [39]. In a subsequent in-vitro study, nitric oxide (NO) donors greatly increased the survival rate of SARS-CoV-infected eukaryotic cells, suggesting direct antiviral effects of NO [39,40]. Due to similarities with the Coronavirus responsible for SARS and COVID-19, scientists indicated the potential effectiveness of iNO therapy.

It is necessary to make the following comments about the safety of the use of NO gas. It reacts with oxygen to form NO₂, which may cause damage to lung tissues. Moreover, NO oxidizes ferrous Hb to form Met-Hb, which is unable to transport and release oxygen to tissues. Based on the present literature and Food and Drug Administration reports, the risks of breathing iNO at 80 ppm for 24
hours are minimal when Met-Hb levels and NO/NO₂ delivery levels are carefully monitored [40]. To improve safety, in the present trial, iNO is administered and monitored by trained clinicians. The NO₂ will be monitored and maintained at levels of below 2 ppm. Met-Hb is continuously monitored by non-invasive CO-oximetry.

Detection of Acetone for Diagnosing Diabetes

Diabetes patients use fat instead of glucose for energy and ketones are produced by the liver during fatty-acid metabolism. The concentrations of breath acetone in diabetes patients are reported to be higher than 1.8 ppm while those of healthy people are lower than 0.8 ppm. Breath acetone concentrations can increase during ketogenic or low carbohydrate diets that are known to induce ketosis. It allows checking the effectiveness of ketosis-based dietary programs for healthy people. Among all other sensing materials, metal oxides show the highest responses to acetone. Various oxide sensing materials mentioned below allow enhancing selectivity and sensitivity to acetone under highly humid atmospheres.

There are Pt, Rh or Ni-loaded TiO₂, SnO₂, nanotubes/hierarchical nanofibers and WO₃ hemitubes/nanofibers, having an average size of 2 to 3 nm [41-43], Pt-loaded [44], Pd-loaded ZnO/ZnCo₂O₄, hollow spheres [42], RuO₂-loaded WO₃ nanofibers [43], Rh₂O³-loaded WO₃ nanofibers [44], and PdO-loaded Co₃O₄, hollow nanocages [45]. These fabricated nanostructures show great promise to be utilized as portable breath sensors for diabetes disease diagnosis. Note that SnO₂, ZnO, Fe₂O₃, WO₃, and other metal oxide gas sensors often show similar responses to acetone, ethanol, and other VOCs. Accordingly, analyses from intoxicated diabetes patients, or the presence of small amounts of alcohol in the mouth, may not provide reliable diagnoses. Pure and catalyst loaded has been used as the most common and representative sensing materials for the selective detection of acetone [46-49].

Detection of H₂S for Diagnosing Halitosis

The degradation of S-containing amino acids in the oral cavity, upper/lower respiratory tract, and alveolar exchange with blood lead to halitosis. It is detectable as highly odorous gases with concentrations less than 1 ppm that can be used to diagnose for hepaticus and metabolic disorder. CuO alone and as additive materials to SnO₂, In₂O₃, and ZnO have been used as the sensing material. The conversion of the p-type semiconducting CuO into metallic CuS leads to the form of junction n-type semiconductor-metallic CuS. The doping of hollow SnO₂ spheres with CuO decreased the humidity dependence of the sensing characteristics to negligible levels without sacrificing high selectivity and sensitivity H₂S at 80% RH. Therefore, CuO is effective both in dry air and exhaled breath.

Liang et al. [50] reported that the CuO-loaded In₂O₃, nanofiber sensor showed reversible H₂S sensing characteristics above 300°C. Doping Mo on ZnO nanowires not only increased selectivity to H₂S but addition significantly enhanced the reversibility of the H₂S sensing characteristics. Ag was also reported to be an effective addition. Yoneda et al. [51] provided a mini review on various techniques for the analysis of halitosis. Some other investigations of the H₂S sensing characteristics reported in [41,50-53].

Investigations of Metal Oxides Biomarkers Sensitive to Hydrogen, Hydrogen Dioxide, Isoprene, and Aldehydes

Hydrogen sensors implemented at Yerevan State University (YSU) [53-55] are highly sensitive. It is important that sensors are very sensitive even at relatively high gas concentrations. Remember that the concentration of hydrogen exhaled by a healthy patient is already about 6%, and with the diseases noted above in the Table 1, this concentration is even higher. Therefore, the use of our hydrogen sensors for biomedical applications is very promising.

As for the hydrogen peroxide H₂O₂ sensors developed at YSU [56-59], the detection of low concentrations of exhaled gas (in the range of less than one to one hundred ppm), which is just characteristic of our sensors, is already required here. In addition, the dependence of the sensor response on gas concentration is linear, which facilitates the processing of data and the design of a meter of the gas concentration. Pure SnO₂ and other metal oxides without corresponding doping have a low sensitivity (response) to gases at a sufficiently high working (operating) temperature of their preliminary heating. In particular, we have shown that the functionalization of the SnO₂ film structures with multilayer carbon nanotubes (MWCNT) and Ru catalysts leads to a remarkable decrease in the sensor operating temperature and a significant increase in the response signal to acetone, methanol, ethanol, isobutane, and toluene vapors. Several complex phenomena take place in such functionalized nanocomposites. Today it is impossible to imagine the full picture, but we must take into account the following: Note that MWCNTs have a developed surface and a nanoscale structure that exposes many parts of the surface with which gases can react; CNTs have a much smaller sensitivity to gases as well as the electrical conductivity of CNTs is much higher than the electrical conductivity of metal oxides. Consequently, the doping of metal oxides with CNTs reduces the resistance of sensitive metal oxide materials and opens up the possibility of more intense passage of charge carriers from one ohmic contact to another. Since the metal oxide film is mainly an n-type semiconductor, and MWCNTs have p-type semiconductor characteristics, many depleted layers are formed in such multi-grain films. Note that each time one depleted region is located on the surface of the metal oxide, and the other is at the interface between the metal oxide nanoparticle and MWCNTs. The formation of nanochannels and heterojunctions leads to increased gas sensitivity of such gas sensors due to a decrease in the work function (barrier height) and an increase in the conductivity of the sensitive layer. The same phenomena were detected in Fe₂O₃ and ZnO samples doped with CNTs [60,61].
The investigations of the response of metal oxide sensors to isoprene are carried out in [62]. Gaseous aldehyde breath biomarkers were proposed [63]. Ni-doped and Co-doped ZnO nanowires, Co$_3$O$_4$ (mesoporous, Cr-doped nanocomposites, and Pd-loaded shell sphere and hierarchical nanosheets), Cr$_2$O$_3$-ZnCr$_2$O$_4$ nanocomposites, NiO-NiMoO$_3$-SnO$_2$ nanocomposites, Cr$_2$O$_3$-ZnO$_2$ film with Co$_3$O$_4$ overlayer are very promising materials for detection of lung cancer [6].

**Detection of Volatile Organic Compounds for a Cancer**

Researchers have investigated different gases of lung cancer by comparing the breaths of healthy people [6,64]. Volatile organic compounds (VOCs) are reported as biomarker gases of the lung, breast, colon and prostate cancers. Note that most lung-cancer biomarker gases, except a few, contain benzene rings. Pure CNT or graphene-based sensing materials generally do not exhibit notable responses to large gases at room temperature or temperatures less than 100°C. P-type semiconductors as gas sensing materials for benzene-derived gases, such as xylene, toluene, and benzene itself, can be used during measurements of lung cancer.

Of course, lung cancer can be diagnosed via the detection of a single biomarker gas. However, to increase diagnosis precision, the diagnosis of lung cancer using the electronic nose technology is preferable.

**Gas Detectors**

Many interesting detectors are developed today for health monitoring and diagnosis –pulsoximeters, diabet measurers, Doppler radar sensors, smartphone sensors with camera and microphone, custom Bio-VOC injection systems etc [65-67]. Such detectors use different methods and phenomena in process of investigations of illnesses, mostly have large sizes and expensive, realize invasive monitoring. The intensive work on the manufacture of new bio-safe small-sized equipment using semiconductor gas sensors for medical applications and diagnose various diseases are carried out in recent years. Requirements for such biomarkers are their high sensitivity, selectivity, and stability to very low concentrations of gases, mainly exhaled by a living organism. Non-invasive diagnostics of the patient, based on the analysis of exhaled air in a special device, allow only to make exhalation and after a few seconds-one minute to get the results of the analysis. The prospect of a non-invasive diagnosis is obvious - full safety from viral hepatitis, AIDS, and other infections.

Note that semiconductor sensors of various gases have been developed in Department of Semiconductor Physics and Microelectronics and the Scientific Center for Semiconductor Devices and Nanoelectronics at YSU. Sensors at YSU are sensitive to vapors of acetone, ammonia, nitrogen oxides, iso-butane, ammonia, hydrogen sulfide, hydrogen, various alcohols, toluene, combustible gases, hydrogen peroxide, propane, propylene glycol, formaldehyde, dimethylformamide, dichloroethane, gasoline, carbon monoxide and smoke arising in the early stages of a fire (see some references above and [68,69]). As part of the NATO grant, small-sized semiconductor sensors for nerve gases of chemical weapons (sarin, mustard gas) have been developed in YSU [70]. Successful tests of such sensors were carried out at the Czech Military Academy. Studies of hydrogen and hydrogen peroxide sensors were carried out jointly with colleagues from the USA, Hungary, Czechia, France and the Republic of Korea. Note that the sensors at YSU are stable in time, have smaller sizes, and cheap.

![Figure 1: Arduino Nano acethone gas detector](image-url)
diagnosis, the adsorption of analyte gases, interference gases, and moisture needs to be significantly improved.

**Conclusion**

One of the most important directions of modern medicine is non-invasive diagnostics of the patient, based on the analysis of exhaled air in a special device. Data on the surveillance capabilities of various diseases in the allocation of specific gases are collected. The potential of various semiconductor chemical resistors made from metal oxide semiconductors to diagnose disease has been reviewed. For disease diagnosis from exhaled breath, pure and catalyst-loaded semiconductor chemical resistors sensing materials for specific biomarker gases are reported. In particular, nano sensors were discussed having the potential to detect asthma, renal disease, diabetes, halitosis, and lung cancer. The humidity and temperature dependencies of various sensing characteristics need to be decreased to negligible levels through the complete understanding of gas-sensing mechanisms and the interaction between moisture and the sensing surface. Corresponding low-cost detectors are developed which can detect small concentrations of exhaled air.
