Constant-Factor Approximation for TSP with Disks

Adrian Dumitrescu∗ Csaba D. Tóth†

Thursday 14th April, 2016

Abstract

We revisit the traveling salesman problem with neighborhoods (TSPN) and present the first constant-ratio approximation for disks in the plane: Given a set of \( n \) disks in the plane, a TSP tour whose length is at most \( O(1) \) times the optimal can be computed in time that is polynomial in \( n \). Our result is the first constant-ratio approximation for a class of planar convex bodies of arbitrary size and arbitrary intersections.

In order to achieve a \( O(1) \)-approximation, we reduce the traveling salesman problem with disks, up to constant factors, to a minimum weight hitting set problem in a geometric hypergraph. The connection between TSPN and hitting sets in geometric hypergraphs, established here, is likely to have future applications.

Keywords: Traveling salesman problem, minimum weight hitting set, approximation algorithm.

1 Introduction

In the Euclidean Traveling Salesman Problem (ETSP), given a set of points in the Euclidean space \( \mathbb{R}^d \), \( d \geq 2 \), one seeks a shortest closed curve (a.k.a. tour) that visits each point. In the TSP with neighborhoods (TSPN), each point is replaced by a point-set, called region or neighborhood, and the TSP tour must visit at least one point in each region, i.e., it must intersect each region. The oldest record that we could trace of this variant goes back to Arkin and Hassin [2]. Since the Euclidean TSP is known to be NP-hard in \( \mathbb{R}^d \) for every \( d \geq 2 \) [21, 22, 38], TSPN is also NP-hard for every \( d \geq 2 \). TSP is recognized as one of the corner-stone problems in combinatorial optimization. Other related problems in geometric network optimization can be found in the two (somewhat outdated) surveys by Mitchell [30, 31].

It is known that the Euclidean TSP admits a polynomial-time approximation scheme in \( \mathbb{R}^d \), where \( d = O(1) \), due to classic results of Arora [3] and Mitchell [29]. Subsequent running time improvements have been obtained by Rao and Smith [39]; specifically, the running time of their PTAS is \( O(f(\varepsilon) n \log n) \), where \( f(\varepsilon) \) grows exponentially in \( 1/\varepsilon \). In contrast, TSPN is generally harder to approximate. Typically, somewhat better approximations are available when the neighborhoods are pairwise disjoint, or fat, or have comparable sizes. We briefly review some of the previous work concerning approximation algorithms for TSPN.

Related work. Arkin and Hassin [2] gave constant-factor approximations for translates of a connected region, and more generally, for neighborhoods of pairwise parallel diameters, where the ratio between the longest and the shortest diameter is bounded by a constant. Dumitrescu and Mitchell [16] extended the above result to connected neighborhoods with comparable diameters. Bodlaender et al. [8] described a PTAS for TSPN with disjoint fat neighborhoods of about the same size in $\mathbb{R}^d$, where $d$ is constant (this includes the case of disjoint unit disks in the plane). Earlier Dumitrescu and Mitchell [19] proposed a PTAS for TSPN with fat neighborhoods of about the same size and bounded depth in the plane, where Spirkl [42] recently reported and filled a gap; see also a follow-up note in [34].

Mata and Mitchell [28] gave a $O(\log n)$ approximation for TSPN with $n$ connected and arbitrarily intersecting neighborhoods in the plane; see also [7]. Elbassioni et al. [19] and Gudmundsson and Levcopoulos [23] improved the running time of the algorithm. The $O(\log n)$-approximation relies on the following early result by Levcopoulos and Lingas [27]: Every (simple) rectilinear polygon $P$ with $n$ vertices, $r$ of which are reflex, can be partitioned in $O(n \log n)$ time into rectangles whose total perimeter is $\log r$ times the perimeter of $P$.

Using an approximation algorithm due to Slavik [41] for Euclidean group TSP, de Berg et al. [6] obtained constant-factor approximations for disjoint fat convex regions (of arbitrary diameters) in the plane. Subsequently, Elbassioni et al. [19] gave constant-factor approximations for arbitrarily intersecting fat convex regions of comparable size. Preliminary work by Mitchell [32] gave a PTAS for planar regions of bounded depth and arbitrary size, in particular for disjoint fat regions. Chan and Jiang [12] gave a PTAS for fat, weakly disjoint regions in metric spaces of constant doubling dimension (combining an earlier QPTAS by Chan and Elbassioni [11] with a PTAS for TSP in doubling metrics by Bartal et al. [4]).

Disks and balls are undoubtedly among the simplest neighborhood types [2, 16, 24]. TSPN for disks is NP-hard, and it remains so for congruent disks, since when the disk centers are fixed and the radius tends to zero, the problem reduces to TSP for points. Regarding approximations, the case of congruent balls is relatively well understood: Given a set of $n$ congruent (say, unit) balls in $\mathbb{R}^d$, a TSP tour whose length is at most $O(1)$ times the optimal can be computed in polynomial time, when $d$ is constant [18]. However, for disks of arbitrary radii and intersections, no constant-ratio approximation was known. Some of the difficulties with disks of arbitrary radii in the plane were uncovered in [17].

Recent work of Dumitrescu and Tóth [18] focused on unbounded neighborhoods, such as lines or hyperplanes: They gave a constant-factor approximation for TSPN with $n$ hyperplanes in $\mathbb{R}^d$ in $O(n)$ time; and a $O(\log^3 n)$-approximation for $n$ lines in $\mathbb{R}^d$ in time polynomial in $n$, where $d$ is constant. In contrast, the current paper considers TSPN with arbitrary disks in $\mathbb{R}^2$, which requires quite different approximation techniques and new ideas.

Degree of approximation. Regarding the degree of approximation achievable, TSPN with arbitrary neighborhoods is generally APX-hard [6 [40], and it remains so even for segments of nearly the same length [19]. The problem is also APX-hard for disconnected neighborhoods [40], such as point-pair neighborhoods [15]. Further, approximating TSPN for (arbitrary) connected neighborhoods in the plane within a factor smaller than 2 is NP-hard [40]. Delineating the class of neighborhoods for which constant-factor approximations are possible remains mysterious, at least at the moment. It is conjectured that approximating TSPN for disconnected regions in the plane within a $O(\log^{1/2} n)$ factor is probably intractable [40]. Similarly, it is conjectured that approximating TSPN for connected regions in $\mathbb{R}^3$ within a $O(\log^{1/2} n)$ factor and for disconnected regions in $\mathbb{R}^3$ within a $O(\log^{2/3} n)$ factor [40] are intractable.
Our results. In this paper we present a polynomial-time (deterministic) algorithm that, given a set of \( n \) disks in \( \mathbb{R}^2 \) (with arbitrary radii and intersections), returns a TSP tour whose length is \( O(1) \) times the optimal.

**Theorem 1.** Given a set of \( n \) disks in the plane, a TSP tour whose length is at most \( O(1) \) times the optimal can be computed in time polynomial in \( n \).

In their seminal paper on TSPN, Arkin and Hassin [2] suggested disks as the most natural type of neighborhood—in which the traveling salesman can meet each potential buyer at some point close to the respective buyer’s location. Here the radius of each disk indicates how much each potential buyer is willing to travel to meet the salesman. While constant-ratio approximations for disks of the same (or comparable) radius [2, 16] and for disjoint disks of arbitrary radii [6] have been obtained early on, the case of disks with arbitrary radii and arbitrary intersections has remained open until now.

2 Preliminaries

We achieve a \( O(1) \)-approximation for TSP with disks by reducing the problem, up to constant factors, to a minimum weight hitting set problem in a geometric hypergraph, for which a constant-factor approximation algorithm was found only recently [13].

**Hitting sets.** Hitting sets are defined in general in terms of hypergraphs (i.e., set systems or range spaces). A hypergraph is a pair \( G = (V, E) \) where \( V \) is a finite vertex set and \( E \subseteq 2^V \) is a finite collection of subsets of \( V \) (called edges). In a geometric (primal) hypergraph, the vertex set \( V \) is a finite set of \( n \) points in Euclidean space \( \mathbb{R}^d \), and all sets in \( E \) are of the form \( V \cap Q \) where \( Q \) is a certain geometric shape of bounded description complexity, e.g., halfspace, ball, triangle, axis-aligned rectangle, etc. Geometric hypergraphs often have nice properties such as bounded VC-dimension or bounded union complexity; see [20, 37].

A hitting set in a hypergraph \( G = (V, E) \) is a subset of vertices \( H \subseteq V \) such that every hyperedge in \( E \) contains some point in \( H \). The minimum hitting set (MHS) problem asks for a hitting set of minimum cardinality in a given hypergraph. The minimum weight hitting set (MWHS) problem asks for a hitting set of minimum weight in a given hypergraph with vertex weights \( w : V \to \mathbb{R}^+ \).

Brönnimann and Goodrich [9] gave a \( O(\log \text{OPT}) \)-approximation for MHS in geometric hypergraphs using LP-relaxations and the fact that geometric hypergraphs have bounded VC-dimension. Clarkson and Varadarajan [14] gave an \( O(\log \log n) \)-approximation for some geometric hypergraphs, by observing a connection between hitting sets and the combinatorial complexity of the union of the corresponding geometric objects. Mustafa and Ray [36] gave a PTAS for MHS with disks and pseudo-disks in the plane using a local search paradigm; see also [1] [10]. However, this method does not seem to extend to the weighted version (MWHS).

Varadarajan [44] gave a \( O(\log \log n) \)-approximation for MWHS, extending the results from [14]. His approach was further extended by Chan et al. [13] who obtained a randomized polynomial-time \( O(1) \)-approximation algorithm for MWHS in geometric hypergraphs of linear union complexity, including geometric hypergraphs defined by disks in \( \mathbb{R}^2 \) [25]; their algorithm can be derandomized [13, Section 3]. Specifically, we use the following result due to Chan et al. [13].

**Theorem 2.** [13 Corollary 1.4 and Section 3] There is a polynomial-time (deterministic) \( O(1) \)-approximation algorithm for the minimum weight hitting set problem for disks in \( \mathbb{R}^2 \).
Definitions. Let $\mathcal{R}$ be a set of regions (neighborhoods) in $\mathbb{R}^2$. An optimal TSP tour for $\mathcal{R}$, denoted by $\text{OPT}(\mathcal{R})$, is a shortest closed curve in the plane that intersects every region in $\mathcal{R}$; when $\mathcal{R}$ is clear from the context, $\text{OPT}(\mathcal{R})$ and $\text{OPT}$ are used interchangeably.

The Euclidean length of a curve $\gamma$ is denoted by $\text{len}(\gamma)$. Similarly, the total (Euclidean) length of the edges of a geometric graph $G$ is denoted by $\text{len}(G)$. The perimeter of a polygon $P$ is denoted by $\text{per}(P)$; the boundary of a region $R$ is denoted by $\partial R$; and the convex hull of a planar set $S$ is denoted by $\text{conv}(S)$.

The distance between two planar point sets $S_1, S_2 \subset \mathbb{R}^2$, is $\text{dist}(S_1, S_2) = \inf \{\text{dist}(s_1, s_2) : s_1 \in S_1, s_2 \in S_2\}$. The distance between a point set $S_1$ and a geometric graph $G$ is defined as $\text{dist}(S_1, G) := \text{dist}(S_1, S_G)$, where $S_G$ is the set of all points at vertices and on the edges of $G$.

Algorithm Outline. Given a set $S$ of $n$ disks in Euclidean plane, we construct a connected geometric graph $G$ that intersects every disk in $S$ and such that $\text{len}(G) = O(\text{len}(\text{OPT}))$. An Eulerian tour of the multi-graph obtained by doubling each edge of $G$ visits each disk and its length is $2\text{len}(G) = O(\text{len}(\text{OPT}))$, as desired.

The graph $G$ is the union of three geometric graphs, $G_1, G_2$ and $G_3$. The graph $G_1$ is an $O(1)$-approximation of an optimal tour for a maximal subset of pairwise disjoint disks in $S$; this step is based on earlier results [6, 19] (Section 3). The graph $G_2$ connects $G_1$ to nearby disks that are guaranteed to be at distance at most $\text{len}(\text{OPT})/n$ from $G_1$. The graph $G_3$ connects any remaining disks to $G_1$; this step is based on recent results on minimum weight hitting sets due to Chan et al. [13] (Section 5).

The interface between TSP and the hitting set problem is established by a quadtree subdivision [5, Ch. 14]. Previously, Arora [3] and Mitchell [33] used quadtrees for approximating Euclidean TSP and TSP with disjoint neighborhoods, respectively. The quadtree variety that we need, a so-called stratified grid, was introduced by Mitchell [33] for certain orthogonal polygons. Here we define stratified grids in a more general setting, for arbitrary geometric graphs (Section 4).

3 Preprocessing

Let $S$ be a set of $n$ disks in the plane. The algorithm first constructs the graphs $G_1$ and $G_2$ as follows (Fig. 1).

1. Select an independent subset $I$, $I \subseteq S$, of pairwise disjoint disks by the following greedy algorithm: Set $I := \emptyset$. Consider the disks in $S$ sorted by increasing radii (with ties broken arbitrarily), and successively place a disk $D \in S$ into $I$ if it is disjoint from all previous disks in $I$.

2. Compute a constant-factor approximate TSP tour $\xi_0$ for $I$ using the algorithm in [6] or [19]. (A PTAS for disjoint disks in the plane is available [16, 42] but not needed for our purpose.) It is clear that $\text{len}(\xi_0) = O(\text{len}(\text{OPT}))$.

3. Let $R$ be a minimum axis-parallel square such that $\text{conv}(R)$ intersects every disk in $S$ (i.e., every disk intersects its boundary or is contained in its interior). $R$ can be computed in $O(n)$ time by linear programming: compute and extend to a square the minimum-width and minimum-height rectangle intersecting every disk, and select the smaller square. Let $r$ denote its side-length; obviously, we have $r \leq \text{len}(\text{OPT})$.

4. Let $G_1$ be the union of $\xi_0$, $R$, and a shortest line segment connecting $\xi_0$ and $R$ (if disjoint).
Figure 1: Left: a set of disks in the plane; the independent set $I$ selected by a greedy algorithm is highlighted; a TSP tour $\xi_0$ for $I$, and a minimum square $R$ intersecting all disks are shown. Middle: $G_1$ is the union of $\xi_0$, $R$, and a shortest line segment connecting them; only the disks in $S_2 \cup S_3$ that do not intersect $G_1$ are shown. Right: a stratified grid for $R$ and $G_1$.

The graph $G_1$ intersects all disks in $I$ and possibly some disks in $S \setminus I$. Our primary interest is in the disks in $S$ that are disjoint from $G_1$.

**Lemma 1.** For every disk $D \in S$, we have $\text{dist}(D, G_1) \leq \text{diam}(D)$.

*Proof.* Let $D \in S$. If $G_1$ intersects $D$, then $\text{dist}(D, G_1) = 0$, and the claim is trivial. Assume that $D$ is disjoint from $G_1$. Since $\xi_0$ intersects every disk in $I$ and $\xi_0 \subseteq G_1$, we have $D \in S \setminus I$. By the greedy choice of $I \subseteq S$, the disk $D$ intersects some disk $D' \in I$ of equal or smaller radius, where $G_1$ intersects $D'$. Consequently, $\text{dist}(D, G_1) \leq \text{diam}(D') \leq \text{diam}(D)$. \hfill $\square$

**Connecting nearby disks to $G_1$.** We partition $S$ into three subsets: let $S_1$ be the set of disks in $S$ that intersect $G_1$; let $S_2$ be the set of disks $D \in S \setminus S_1$ such that $\text{dist}(D, G_1) \leq \frac{r}{n}$; and let $S_3 = S \setminus (S_1 \cup S_2)$. Let $G_2$ be a graph that consists of $|S_2|$ line segments: specifically for every $D \in S_2$, $G_2$ contains a shortest segment connecting $D$ and $G_1$. Then $\text{len}(G_2) = \sum_{D \in S_2} \text{dist}(D, G_1) \leq |S_2| \cdot \frac{r}{n} \leq r \leq \text{len}(\text{OPT})$. By construction, we have

$$\text{dist}(D, G_1) > \frac{r}{n} \text{ for every } D \in S_3.$$  \hfill (1)

By Lemma 1 and inequality (1) we have

**Corollary 1.** For every disk $D \in S_3$, we have $\text{diam}(D) > \frac{r}{n}$.

In the next section, we show how to find a geometric graph $G_3$ such that $G_3$ intersects every disk in $S_3$ and $G_1 \cup G_3$ is connected (note, however, that $G_3$ need not be connected).

### 4 Stratified Grids

Recall that we have a geometric graph $G_1$, and a set $S_3$ of at most $n$ disks in the interior of an axis-aligned square $R$ of side-length $r$, $r \leq \text{len}(\text{OPT})$, satisfying (1). Let $\text{OPT}(S_3, G_1)$ denote a geometric graph $\Gamma$ of minimum length such that $G_1 \cup \Gamma$ is connected and intersects every disk in $S_3$. Note that $\text{len}(\text{OPT}(S_3, G_1)) \leq \text{len}(\text{OPT}(S_3)) \leq \text{len}(\text{OPT})$, for every $G_1$.

In Sections 5 and 6 we use hitting sets to compute a $O(1)$-approximation of $\text{OPT}(S_3, G_1)$. Similarly to a quadtree decomposition, we recursively construct a subdivision of $R$ into squares of side-lengths $r/2^i$, for $i = 0, 1, \ldots, \lfloor \log n \rfloor$. Refer to Fig. 1(right).
Previously, Mitchell \cite{33} used a similar quadtree decomposition for TSPN with disjoint regions in the plane, coined the term “stratified grid,” and derived several basic properties of quadtrees that we rederive here. Specifically, he proved analogues of Lemmas \textcircled{2} and \textcircled{5} for the problem studied in \cite{33}. However, Mitchell used stratified grids only for special types of orthogonal polygons, called histograms \cite{26}; here we generalize this tool to arbitrary geometric graphs.

The following algorithm subdivides a square $Q$ unless it is too small (i.e., $\text{diam}(Q) < \frac{r}{2n}$) or it is relatively far from $G_1$ (i.e., $\text{diam}(Q) < \text{dist}(Q,G_1)$).

**Stratify**($R,G_1$). Let $L$ be a FIFO queue and $Q$ be a set of axis-aligned squares. Set $L = (R)$ and $Q = \emptyset$. Repeat the following while $L$ is nonempty. Set $Q \leftarrow \text{dequeue}(L)$. If $\text{diam}(Q) \geq \max(\frac{r}{2n}, \text{dist}(Q,G_1))$, then subdivide $Q$ into four congruent axis-aligned squares, and enqueue them onto $L$. Otherwise, let $Q \leftarrow Q \cup \{Q\}$. Return $Q$.

It is worth noting that $Q$ does not directly depend on the disks in $S_3$, but only indirectly, via $G_1$. By construction, the squares in $Q$ are interior-disjoint, and every square in $Q$ has diameter at least $r/(4n)$. Consequently, the number of squares in $Q$ is $O(n^2)$. Thus the algorithm **Stratify**($R,G_1$) runs in polynomial time in $n$, since $O(n^2)$ squares are enqueued onto $L$, and dist($Q,G_1$) can be computed in polynomial time for all $Q \in L$. We show that the squares in $Q$ have a property similar to the disks in $S_3$ (cf. Lemma \textcircled{1}): only larger squares can be farther from $G_1$.

**Lemma 2.** For every square $Q \in Q$, we have $\text{dist}(Q,G_1) \leq 3 \text{ diam}(Q)$.

**Proof.** Put $q = \text{diam}(Q)$. Recall that $Q$ is obtained by subdividing a square $Q'$, $Q \subset Q'$, with $\text{diam}(Q') = 2q$. Since $Q'$ is subdivided by the algorithm, we have $\text{diam}(Q') \geq \max(\frac{r}{2n}, \text{dist}(Q',G_1))$. Since $\text{dist}(p',Q) \leq q$ for every point $p' \in Q'$, the triangle inequality yields $\text{dist}(Q,G_1) \leq 3q$. \hfill $\Box$

Figure 2: Left: a square $Q$ of the stratified grid, and the graph $\gamma(Q)$. Right: a polygonal curve $\alpha$; the intersections of $\alpha$ with horizontal (resp., vertical) edges of the stratified grid are marked with empty (resp., full) dots.

For every square $Q \in Q$, we define a graph $\gamma(Q)$ that consists of the boundary of $Q$ and a shortest line segment from $Q$ to $G_1$; see Fig. 2(left). By Lemma 2, we have $\text{len}(\gamma(Q)) \leq (3 + 2\sqrt{2}) \text{ diam}(Q)$; on the other hand, $\text{len}(\gamma(Q)) \geq \text{per}(Q) = 2\sqrt{2} \text{ diam}(Q)$, and so we have the following.

**Corollary 2.** For every $Q \in Q$, we have $\text{len}(\gamma(Q)) = \Theta(\text{diam}(Q))$.  

6
The following observation is crucial for reducing the problem of approximating $\text{OPT}(S_3,G_1)$ to a minimum weight hitting set problem.

**Lemma 3.** If a square $Q \in Q$ intersects a disk $D \in S_3$, then

(i) $\text{diam}(Q) \leq 2 \text{diam}(D)$, and

(ii) $D$ intersects the boundary of $Q$ (and the graph $\gamma(Q)$ in particular).

**Proof.** (i) Since $Q \in Q$, Algorithm \textbf{Stratify}$(R,G_1)$ did not subdivide $Q$, and so we have $\text{diam}(Q) < \frac{r}{2n}$ or $\text{diam}(Q) < \text{dist}(Q,G_1)$. If $\text{diam}(Q) < \frac{r}{2n}$, then Corollary 1 yields

$$\text{diam}(Q) < \frac{r}{2n} < \frac{r}{n} < \text{diam}(D) < 2 \text{diam}(D).$$

If $\text{diam}(Q) < \text{dist}(Q,G_1)$, then $\text{dist}(Q,G_1) \leq \text{dist}(D,G_1) + \text{diam}(D)$ follows from the intersection condition and the triangle inequality. Consequently,

$$\text{diam}(Q) < \text{dist}(Q,G_1) \leq \text{dist}(D,G_1) + \text{diam}(D) \leq 2 \text{diam}(D),$$

where the last inequality holds by Lemma 1.

(ii) Suppose, to the contrary, that the boundary of $Q$ is disjoint from $D$, hence $D$ lies in the interior of $Q$. This immediately implies

$$\text{dist}(Q,G_1) \leq \text{dist}(D,G_1).$$

Since $Q \in Q$, Algorithm \textbf{Stratify}$(R,G_1)$ did not subdivide $Q$, and so we have $\text{diam}(Q) < \frac{r}{2n}$ or $\text{diam}(Q) < \text{dist}(Q,G_1)$. If $\text{diam}(Q) < \frac{r}{2n}$, Corollary 1 yields $\text{diam}(Q) < \frac{r}{2n} < \frac{r}{n} < \text{diam}(D)$. If $\text{diam}(Q) < \text{dist}(Q,G_1)$, then the combination of (2) and Lemma 1 yield

$$\text{diam}(Q) < \text{dist}(Q,G_1) \leq \text{dist}(D,G_1) < \text{diam}(D).$$

In both cases, we have shown that $\text{diam}(Q) < \text{diam}(D)$. Therefore $D$ cannot lie in the interior of $Q$, which contradicts the assumption. \hfill $\square$

Recall that the squares in $Q$ can only intersect at common boundary points; we call such squares adjacent.

**Lemma 4.** If two squares $Q_1,Q_2 \in Q$ are adjacent and $\text{diam}(Q_1) \leq \text{diam}(Q_2)$, then

$$\frac{1}{2} \text{diam}(Q_2) \leq \text{diam}(Q_1) \leq \text{diam}(Q_2) \leq 2 \text{ diam}(Q_1).$$

**Proof.** If $\text{diam}(Q_1) = \text{diam}(Q_2)$, the inequalities are satisfied. We may thus assume that $\text{diam}(Q_1) < \text{diam}(Q_2) = q$. Then Algorithm \textbf{Stratify}$(R,G_1)$ subdivided a square $Q'_1$ such that $Q_1 \subset Q'_1$, $\text{diam}(Q'_1) \leq q$, and $Q'_1 \cap Q_2 \neq \emptyset$. The algorithm subdivided $Q'_1$ but did not subdivide $Q_2$. This implies

$$q \geq \max \left( \frac{r}{2n}, \text{dist}(Q'_1,G_1) \right) \quad \text{and} \quad q < \max \left( \frac{r}{2n}, \text{dist}(Q_2,G_1) \right).$$

The first inequality yields $q \geq \max(\frac{r}{2n}, \text{dist}(Q'_1,G_1)) \geq \frac{r}{2n}$, and then the second inequality yields $q < \max(\frac{r}{2n}, \text{dist}(Q_2,G_1)) = \text{dist}(Q_2,G_1)$. Consequently, $\text{dist}(Q'_1,G_1) \leq q \leq \text{dist}(Q_2,G_1)$.

Since $Q'_1$ and $Q_2$ intersect, and their diameters are at most $q$, the triangle inequality yields $|\text{dist}(Q'_1,G_1) - \text{dist}(Q_2,G_1)| \leq q$. It follows that

$$q < \text{dist}(Q_2,G_1) \leq \text{dist}(Q'_1,G_1) + q \leq 2q.$$
Similarly, since $Q_1$ and $Q_2$ intersect, $\text{dist}(Q_1, G_1) \geq \text{dist}(Q_2, G_1) - \text{diam}(Q_1) > q - \text{diam}(Q_1)$. Combining with Lemma 2, we get

$$3 \text{diam}(Q_1) \geq \text{dist}(Q_1, G_1) > q - \text{diam}(Q_1),$$

that is, $\text{diam}(Q_1) > q/4$. Finally, recall that the ratio between the diameters of any two squares in $Q$ is a power of 2. Therefore $q/4 < \text{diam}(Q_1) < q$ yields $\text{diam}(Q_1) = q/2$, as required.

\section{Hitting Sets for Squares and Disks}

For the graph $G_1$ and the set of disks $S_3$, we define a hypergraph $\mathcal{G} = (Q, E)$, where the vertex set is the set $Q$ of squares in the stratified grid; and for every disk $D \in S_3$, the set of squares in $Q$ that intersect $D$ forms a hyperedge in $E$. Thus, a subset $H \subseteq Q$ of squares is a hitting set in the hypergraph $\mathcal{G}$ if and only if every disk in $S_3$ intersects some square in $H$.

For every hitting set $H$, the geometric graph $\Gamma = \cup_{Q \in H} (Q)$ intersects every disk in $S_3$ by Lemma 3 and $G_1 \cup \Gamma$ is connected by construction. Let the weight of a square $Q \in \mathcal{G}$ be $w(Q) = \text{diam}(Q)$. In this section, we show that the minimum-weight hitting set for $\mathcal{G} = (Q, E)$ is a $O(1)$-approximation for $\text{OPT}(S_3, G_1)$. The following technical lemma considers a single curve (i.e., a Jordan arc). For a curve $\alpha$, let $Q(\alpha)$ denote the set of squares in $Q$ that intersect $\alpha$. Refer to Fig. 2(right).

\begin{lemma}
Let $\alpha$ be a directed polygonal curve whose start and end points lie on $G_1$. If $\alpha$ intersects at least one disk in $S_3$, then $\text{len}(\alpha) = \Omega(\sum_{Q \in Q(\alpha)} \text{diam}(Q))$.
\end{lemma}

\begin{proof}
By \cite{ref}, we have $\text{dist}(D, G_1) > \frac{r}{n}$ for every disk $D \in S_3$. Since $\alpha$ intersects at least one disk in $S_3$, we have $\text{len}(\alpha) \geq \frac{2r}{n}$.

Let $A = (Q_0, Q_1, \ldots, Q_m)$ be the sequence of distinct squares that intersect $\alpha$ in the order in which they are first encountered by $\alpha$ (with no repetitions and ties broken arbitrarily). Since $Q_0$ intersects $G_1$, we have $\text{diam}(Q_0) < \max(\frac{r}{3n}, 0) = \frac{r}{2n}$, and consequently

$$\text{len}(\alpha) \geq \frac{2r}{n} \geq 4 \text{diam}(Q_0). \quad (3)$$

Let $B = (Q_{\sigma(0)}, Q_{\sigma(1)}, \ldots, Q_{\sigma(\ell)})$ be the subsequence of $A$ such that $\sigma(0) = 0$ and a square $Q_1$, $1 \leq i \leq m$, is added to $B$ if it is disjoint from $Q_j$ for all $0 \leq j < i$. By construction, $B$ consists of pairwise disjoint squares, and every square in $A$ is either in $B$ or adjacent to some square in $B$. By Lemma 3, the sizes of adjacent squares in $Q$ differ by a factor of at most 2. Consequently, each square in $Q$ is adjacent to at most 12 squares in $Q$ (at most two along each side and at most one at each corner). It follows that

$$\sum_{i=0}^{m} \text{diam}(Q_i) = \Theta \left( \sum_{j=0}^{\ell} \text{diam}(Q_{\sigma(j)}) \right). \quad (4)$$

For $j = 0, \ldots, \ell$, let $p_{\sigma(j)}$ be the first intersection point of $\alpha$ with $Q_{\sigma(j)}$. For two points $p, q \in \alpha$, denote by $\alpha(p, q)$ the portion of $\alpha$ between $p$ and $q$. Since the squares in $B$ are pairwise disjoint, and the sizes of adjacent squares differ by at most a factor of 2 (Lemma 4), we have

$$\alpha(p_{\sigma(j)}, p_{\sigma(j+1)}) \geq |p_{\sigma(j)}p_{\sigma(j+1)}| \geq \frac{1}{2\sqrt{2}} \max(\text{diam}(Q_{\sigma(j)}), \text{diam}(Q_{\sigma(j+1)}))$$

for \( j = 0, \ldots, \ell - 1 \). Consequently, if \( \ell \geq 1 \), we have

\[
\text{len}(\alpha) = \sum_{j=0}^{\ell-1} \alpha(p_{\sigma(j)}, p_{\sigma(j+1)}) = \Omega \left( \sum_{j=0}^{\ell} \text{diam}(Q_{\sigma(j)}) \right).
\]

The combination of (3), (4), and (5) yields \( \text{len}(\alpha) = \Omega(\sum_{i=0}^{m} \text{diam}(Q_i)) \), as required.

**Lemma 6.** If \( \Gamma \) is a geometric graph such that \( \Gamma \) intersects every disk in \( S_3 \) and \( G_1 \cup \Gamma \) is connected, then there is a hitting set \( \mathcal{H} \subset Q \) for \( \mathcal{G} = (Q, E) \) such that

\[
\text{len}(\Gamma) = \Omega \left( \sum_{Q \in \mathcal{H}} \text{diam}(Q) \right).
\]

**Proof.** Let \( \mathcal{H} \) be the set of squares in \( Q \) that intersect \( \Gamma \), and observe that \( \mathcal{H} \) is a hitting set for \( \mathcal{G} \). For each connected component \( C \) of \( \Gamma \), let \( \alpha \) be a directed polygonal curve that starts and ends at some points in \( G_1 \cap C \) and traverses every edge of \( C \) at least once and at most twice. Then \( \text{len}(C) \geq \frac{1}{2} \text{len}(\alpha) \), and \( \text{len}(\alpha) = \Omega(\sum_{Q \in Q(\alpha)} \text{diam}(Q)) \) by Lemma 5. Summation over all the components of \( \Gamma \) yields (6).

Recall that \( \text{OPT}(S_3, G_1) \) is a geometric graph \( \Gamma \) of minimum length such that \( G_1 \cup \Gamma \) is connected and intersects every disk in \( S_3 \). Let \( W_0 \) denote the minimum weight of a hitting set in the hypergraph \( \mathcal{G} \). The main result of this section is the following.

**Corollary 3.** We have \( W_0 = O(\text{len}(\text{OPT}(S_3, G_1))) \).

**Proof.** Invoke Lemma 6 with \( \Gamma = \text{OPT}(S_3, G_1) \). Then \( \mathcal{G} \) has a hitting set \( \mathcal{H} \subset Q \) of weight \( \sum_{Q \in \mathcal{H}} \text{diam}(Q) = O(\text{len}(\Gamma)) = O(\text{len}(\text{OPT}(S_3, G_1))) \). This is clearly an upper bound on the minimum weight \( W_0 \) of a hitting set in \( \mathcal{G} \).

6 Hitting Sets for Points and Disks

In Section 5, we defined a hypergraph \( \mathcal{G} = (Q, E) \) for squares and disks; that is, the vertices are squares in \( Q \) and the hyperedges are the squares intersecting a disk in \( S_3 \). In order to apply Theorem 2 by Chan et al. [13], we reduce the problem to a traditional geometric hypergraph problem, where the vertices are points in \( \mathbb{R}^2 \) and a hyperedge corresponds to the set of points contained in a disk \( D \in S_3 \).

For each square \( Q \in Q \), we define a set of 25 sentinel points, and show (Lemma 7) that if a disk \( D \in S_3 \) intersects \( Q \), then \( D \) contains one of the sentinel points of \( Q \). A constant number of sentinels suffice if none of the disks intersecting \( Q \) is too small, and indeed, Lemma 3 has shown that this is the case.

For a square \( Q \in Q \), where \( Q = [a, a+h] \times [b, b+h] \), let the 25 sentinel points be \( (a+ih/2, b+jh/2) \) for all \( i, j \in \{-1,0,1,2,3\} \); see Fig. 3(left).

**Lemma 7.** If a disk \( D \in S_3 \) intersects a square \( Q \in Q \), then \( D \) contains a sentinel point corresponding to \( Q \).

**Proof.** Assume that a disk \( D \in S_3 \) intersects a square \( Q \in Q \) of side length \( h \); refer to Fig. 3(right). By Lemma 3, \( \text{diam}(Q) \leq 2 \text{diam}(D) \). By scaling down \( D \) from an arbitrary center in \( D \cap Q \), we find a disk \( D' \) intersecting \( Q \) with \( \text{diam}(D') = \frac{1}{2} \text{diam}(Q) \). The inscribed axis-aligned square \( Q' \) of
Figure 3: Left: the set of 25 sentinel points for a square $Q$. Right: a disk $D \in S_3$ intersects a square $Q \in \mathcal{Q}$.

$D'$ has $\text{diam}(Q') = \frac{1}{2} \text{diam}(Q)$. That is, the side-length of $Q'$ is $h/2$, and $\text{dist}(Q', Q) \leq (\sqrt{2} - 1)h$.

Since the sentinels of $Q$ form a section of a square lattice of (the same) side-length $h/2$, within distance $\frac{\sqrt{2}}{2} h$ from $Q$, some sentinel of $Q$ lies in $Q'$, and hence in $D' \subseteq D$, as claimed.

We define a new weighted hypergraph $G' = (V', E')$, where $V'$ is the union of sentinel point sets for all $Q \in \mathcal{Q}$ that lie in $R$ (sentinels in the exterior of $R$ are discarded); and each hyperedge in $E'$ is the set of sentinels in $V'$ contained in a disk $D \in S_3$. Note that a sentinel $s \in V'$ may correspond to several squares in $Q$. Let the weight of a sentinel $s \in V'$ be the sum of the diameters of the squares $Q \in \mathcal{Q}$ that correspond to $s$. Hence the total weight of all sentinels is at most $25 \sum_{Q \in \mathcal{Q}} \text{diam}(Q)$.

We next derive a bound on the weight of each sentinel.

**Lemma 8.** For every $Q \in \mathcal{Q}$, the weight of every sentinel corresponding to $Q$ is $O(\text{diam}(Q))$.

**Proof.** By Lemma 4, the side-lengths of adjacent squares of the stratified grid differ by at most a factor of 2. Consequently, every sentinel in $V'$ corresponding to a square $Q \in \mathcal{Q}$ is contained in $Q$ or in a square of $Q$ adjacent to $Q$.

Let $s \in V'$ be a sentinel. Then $s$ may correspond to all squares in $Q$ that contain $s$, and to adjacent squares in $Q$. Every point is contained in at most 4 squares of $Q$, whose side-lengths differ by a factor of at most 2; and they are each adjacent to $O(1)$ additional squares whose side-lengths differ by another factor of at most 2. Overall, $s$ corresponds to $O(1)$ squares in $Q$ whose side-lengths differ by a factor of $\Theta(1)$. Therefore, the weight of $s$ is $O(\text{diam}(Q))$ for every square $Q \in \mathcal{Q}$ corresponding to $s$.

By Theorem 2 there is a polynomial-time $O(1)$-approximation algorithm for MWHS on $\mathcal{G}' = (V', E')$. It remains to show that a $O(1)$-approximation for MWHS on the hypergraph $\mathcal{G}' = (V', E')$ provides a $O(1)$-approximation for MWHS on the hypergraph $\mathcal{G} = (\mathcal{Q}, E)$.

**Lemma 9.** 1. For every hitting set $\mathcal{H} \subseteq \mathcal{Q}$ for $\mathcal{G}$, the set $H'$ of sentinels in $V'$ corresponding to the squares $Q \in \mathcal{H}$ is a hitting set for $\mathcal{G}' = (V', E')$ of weight $O(\sum_{Q \in \mathcal{H}} \text{diam}(Q))$.

2. For every hitting set $H' \subseteq V'$ for $\mathcal{G}'$, the set $\mathcal{H}$ of squares $Q \in \mathcal{Q}$ that contain the sentinel points in $H'$ is a hitting set for $\mathcal{G}$ of weight $O(\sum_{s \in H'} w(s))$.

**Proof.** (1) If $\mathcal{H}$ is a hitting set for $\mathcal{G}$, then every disk $D \in S_3$ intersects some square $Q \in \mathcal{H}$. By Lemma 7, $D$ contains one of the sentinels of $Q$. Consequently, every disk $D \in S_3$ contains a sentinel in $H'$. Every square $Q \in \mathcal{H}$ corresponds to 25 sentinels, each of weight $O(\text{diam}(Q))$ by Lemma 8. The weight of $H'$ is $O(\sum_{Q \in \mathcal{H}} \text{diam}(Q))$. 
If $H'$ is a hitting set for $\mathcal{G}'$, then every disk $D \in S_3$ contains some point $s \in H'$. The point $s$ lies in a square $Q \in \mathcal{Q}$ of the stratified grid, which is in $\mathcal{H}$. Consequently, every disk $D \in S_3$ intersects some square $Q \in \mathcal{H}$. By construction, the weight of each sentinel $s$ is the sum of weights of the corresponding squares in $Q$, including all squares in $Q$ that contain $s$. Therefore, the weight of $\mathcal{H}$ is at most $\sum_{s \in H'} w(s)$, as required.

We are now ready to prove Theorem 1 by analyzing the constructed graph $G = G_1 \cup G_2 \cup G_3$.

Proof of Theorem 1. Let $S$ be a set of $n$ disks in $\mathbb{R}^2$. Compute an independent set $I \subset S$ as described in Section 3, and a TSP tour $\xi_0$ for $I$ with $\text{len}(\xi_0) = O(\text{len}(\text{OPT}))$ by [6, 19]. Compute the graph $G_1$ with $\text{len}(G_1) = O(\text{len}(\text{OPT}))$, and the partition $S = S_1 \cup S_2 \cup S_3$ as described in Section 3. The graph $G_1$ intersects the disks in $S_1$.

Construct the graph $G_2$, which contains a shortest segment between $G_1$ and every disk $D \in S_2$. The length of this graph is $\text{len}(G_2) = \sum_{D \in S_2} \text{dist}(D, G_1) \leq |S_2| \cdot \frac{r}{n} \leq r \cdot \text{len}(\text{OPT})$.

Compute the stratified grid $\mathcal{Q}$, and construct the weighted hypergraph $\mathcal{G}' = (V', E')$, where $V'$ is the set of sentinel points for all squares $Q \in \mathcal{Q}$; the weight of a sentinel $s$ is the sum of diameters of the corresponding squares $Q \in \mathcal{Q}$, and for every disk $D \in S_3$, the set of sentinels lying in $D$ forms a hyperedge in $E'$. Use the algorithm by Chan et al. [13] to compute a hitting set $H'$ for $\mathcal{G}'$ whose weight is $O(1)$ times the minimum. Let $\mathcal{H}$ be the set of squares in $\mathcal{Q}$ containing the sentinels in $H'$. By Lemma 9, $\mathcal{H}$ is a hitting set for the hypergraph $\mathcal{G} = (Q, E)$ whose weight is at most $O(1)$ times the minimum $W_0$. Put $G_3 = \cup_{Q \in \mathcal{H}} (Q)$. Then $G_3$ intersects every disk in $S_3$ by Lemma 3 and $\text{len}(G_3) = \Theta(\sum_{Q \in \mathcal{H}} \text{diam}(Q)) = \Theta(W_0)$ by Corollary 2. Finally, Corollary 3 yields $\text{len}(G_3) = O(\text{len}(\text{OPT}(S_3, G_1)))$. By the definition of $\text{OPT}(S_3, G_1)$, we have $\text{len}(\text{OPT}(S_3, G_1)) \leq \text{len}(\text{OPT}(S_3)) \leq \text{len}(\text{OPT})$, and consequently $\text{len}(G_3) = O(\text{len}(\text{OPT}))$.

Note that the graph $G = G_1 \cup G_2 \cup G_3$ is connected by construction, it intersects every disk in $S = S_1 \cup S_2 \cup S_3$, and $\text{len}(G) = \text{len}(G_1) + \text{len}(G_2) + \text{len}(G_3) = O(\text{len}(\text{OPT}))$. Consequently, an Eulerian tour of the multi-graph containing each edge of $G$ twice visits each disk and its length is $2\text{len}(G) = O(\text{len}(\text{OPT}))$, as required.

Since all the above steps run in polynomial time (recall that the algorithm $\text{Stratify}(R, G_1)$ runs in time that is polynomial in $n$), the constant-factor approximation algorithm for TSP with disks runs in polynomial time.

7 Conclusion

In this paper, we obtained the first constant-ratio approximation for TSP with disks in the plane. This is the first result of this kind for a class of planar convex bodies of arbitrary size that can intersect in an arbitrary fashion. In light of the connection we established between TSPN and MWHS in geometric hypergraphs, the following question emerges:

1. Besides regions of linear union complexity (e.g., disks and pseudo-disks), what other types of regions admit a constant-factor approximation for the minimum weight hitting set problem?

Obviously, a constant-factor approximation for MWHS with a certain type of neighborhoods does not automatically imply a constant-factor approximation for TSPN with the same type of neighborhoods. We conclude with a few, perhaps the simplest still unsolved questions on TSPN that we could identify:

1 A set of regions $\mathcal{R}$ consists of pseudo-disks, if every pair of regions $\omega_1, \omega_2 \in \mathcal{R}$ satisfies the pseudo-disk property: the sets $\omega_1 \setminus \omega_2$ and $\omega_2 \setminus \omega_1$ are connected [2, p. 293]. Equivalently, the boundaries $\partial \omega_1$ and $\partial \omega_2$ have at most two proper intersection points.
2. Is there a constant-factor approximation algorithm for TSP with a set of objects of linear union complexity, e.g., pseudo-disks?

3. Is there a constant-factor approximation algorithm for TSP with convex bodies in the plane?\textsuperscript{2}

4. Is TSP with disks in the plane \(\text{APX-hard}\)? Is TSP with convex bodies in the plane \(\text{APX-hard}\)?

5. Is there a constant-factor approximation algorithm for TSP with balls (of arbitrary radii) in \(\mathbb{R}^d\), in fixed dimension \(d \geq 3\)?
