(Dated: March 22, 2021)

We study the role of driving in an initial maximally entangled state evolving under the presence of a structured environment in a weak and strong regime. We focus on the enhancement and degradation of maximal Concurrence when the system is driven on and out of resonance for a general evolution, as well as the effect of adding a transverse coupling among the particles of the model. We further investigate the role of driving in the acquisition of a geometric phase for the maximally entangled state. As the model studied herein can be used to model experimental situations such as hybrid quantum classical systems feasible with current technologies, this knowledge can aid the search for physical setups that best retain quantum properties under dissipative dynamics.

PACS numbers:

Two-qubit states are the simplest quantum mechanical systems displaying entanglement. For a bipartite system, it is important to know whether the system is entangled, separable, classically correlated or quantum correlated. As a valuable resource in quantum information processing, entanglement attracts much attention from researchers either in theory or in experiment and much progress concerning this issue has been achieved [1]. However, the presence of an environment can destroy all traces of quantumness of the system. All real world quantum systems interact with their surrounding environment to a greater or lesser extent. As the quantum system is in interaction with an environment, a degradation of pure states into mixtures takes place. No matter how weak the coupling that prevents the system from being isolated, the evolution of an open quantum system is eventually plagued by nonunitary features like decoherence and dissipation. Nowadays, decoherence stands as a serious obstacle in quantum information processing. Likewise, very interesting effects occur regarding their entangling properties when two qubits and external environments are considered. For example, two qubits interacting with two different baths exhibit sudden death of entanglement (ESD) [2], being more pronounce at finite temperature [3] and in the presence of external driving [4]. This means a major obstacle in building a quantum computer since it can be more difficult to maintain quantum correlations when qubits interact with different reservoirs and are locally driving by single-qubit quantum gates. If qubit-qubit interactions are also considered, another interesting feature of entanglement called “steady-state generation of entanglement” takes place [5].

The nonintuitive character of entanglement derives from the fact that it affects a bipartite system although it is subject only to local interactions. Entanglement, however, is a characteristic of the whole system, has a dynamics that can not be understood by just adding the sum of the local effects. The qubit-qubit coupling is established either directly, through mutual inductances and capacitances, or as a second-order effect, due to the interaction through a common environment.

The possibility of exploiting the environment as a resource for control has opened a new door in the manipulation of open quantum systems. The generation and stabilization of entanglement is one of the main challenges for quantum information applications. The dynamical behavior of correlations in the bipartite system depends on the noise produced by the environment. Many different approaches have studied the entanglement properties of bipartite systems in different frameworks. In [6], authors have studied quantum correlations in a two-qubit system coupled to either a common bath or two different baths, focusing on environmental memory effects induced on the bipartite system. In [7], it has been proposed the used of the Quantum Zeno effect to protect the degradation of the entanglement for two atoms in a lossy resonator. In [5], the interplay of driving and decoherence in a bipartite system under the secular approximation for a dephasing model has been studied. In [8], authors numerically studied the generation of a driven-dissipative steady entanglement state for solid state qubits driven by periodic fields, in a dephasing model. Furthermore, in [9] authors focused on driving the open quantum system from an initial separable state to an entangled target state by exploiting the environment as a resource for control. All of these approaches had to resort to simplified analytical approaches or environmental models so as to derive master equations and obtain the dynamical behavior of the bipartite system under particular situations.

An effective method that avoids approximations was developed by Tanimura [10] who established a set of hierarchical equations that includes all order of system-bath interactions. System-bath correlations are fully accounted during the time evolution, as compared to the traditional master equation treatments where correlations are truncated at second order. The information
concerning the system-bath coherence is stored in the hierarchical elements, which allows us to simulate the quantum entangled dynamics between the system and the environment beyond any analytical approximation. In [11], authors used the hierarchy equation model to study two noninteracting qubits embedded in a bosonic environment. Therein, they showed the discrepancy between the results obtained in a resonant case with those derived by using the rotating wave approximation for good and bad cavities. In this manuscript, we extend this model to a driven bipartite system, say two qubits interacting with a common bath and among them (if desired), driven at and off resonance. The importance of the driven two-state model is especially pronounced in quantum computation and quantum technologies, where one or more driven qubits constitute the basic building block of quantum information processing.

We consider two qubits independently coupled to a structured environment. The total Hamiltonian which describes this model reads (we set \( \hbar = 1 \) from here on):

\[
\hat{H} = \hat{H}_S(t) + \hat{H}_I + \hat{H}_E,
\]

with

\[
\hat{H}_S = \omega_1(t)\sigma^1_1 \sigma^1_2 \otimes 1_2 + \omega_2(t)\sigma^1_1 \sigma^2_2 + \frac{J}{2}(\sigma^1_+ \otimes \sigma^2_+ + \sigma^1_- \otimes \sigma^2_-) \\
\hat{H}_I = (\sigma^2_+ \otimes 1_2 + 1_1 \otimes \sigma^2_+) \sum_k (g_k b_k + g_k^* b_k^\dagger) \\
\hat{H}_E = \sum_k \delta \omega_k b_k^\dagger b_k,
\]

where \( \delta \omega_k = \omega_1(t) + \delta \omega_2(t) \) are the time-dependent frequencies.

We shall assume they have the following form:

\[
\omega_1(t) = \Omega_1 + \Delta_1 \cos(\theta_D t + \varphi_1), \quad \text{and} \quad \omega_2(t) = \Omega_2 + \Delta_2 \cos(\theta_D t + \varphi_2)
\]

where an arbitrary driving field is applied over each atom 1 or 2, with driving frequency \( \theta_D \) (allowing time-dependent energy difference between states |0⟩ and |1⟩ of each two-level particle). The exact dynamics of the system in the interaction picture has been derived as in [10, 11]. If the qubits and the bath are initially in a separable state, i.e., \( \rho(0) = \rho_x(0) \otimes \rho_y(0) \), the formal solution is:

\[
\hat{\rho}_S(t) = \mathcal{T} \exp \left\{ -\int_0^t dt_2 \int_0^{t_2} dt_1 \hat{V}(t_2)^* \right\} \rho_x(0) \]

where \( \mathcal{T} \) implies the chronological time-ordering operator and we have introduced the following notation \( A^x B = \hat{A}^x \hat{B} = \hat{B} \hat{A}^x \).
where we have defined dimensionless parameters variables $\tau = \lambda t$ and $x = \bar{x}/\lambda$ (where $x$ is any parameter with units of energy in the model described). The subscript $\tilde{n} = (n_1, n_2)$ with integers numbers $n_{1(2)} \geq 0$, and $\rho_{\hat{S}}(t) \equiv \rho_{0,0}(t)$. We want to emphasize that the “physical” solution is encoded in $\rho_{0,0}(t)$ and all other $\rho_{\tilde{n}}(\tau)$ with $\tilde{n} \neq (0,0)$ are auxiliary operators, just defined in order to solve the system. The vectors $\bar{e}_1 = (1,0)$, $\bar{e}_2 = (0,1)$ and $\bar{\nu} = (\nu_1, \nu_2) = (1 - i\Omega_0, 1 + i\Omega_0)$. This set of linear differential equations can be solved by the use of a Runge Kutta routine. It is important to mention that for numerical computations, the hierarchy equations must be truncated for large $\tilde{n}$. The hierarchy terminator equation is similar to that of Eq. (9) for the term $\tilde{N}$, and the corresponding term related to $\rho_{\tilde{N} + \bar{e}_k}$ is dropped [10]. In all simulations presented in this manuscript, we have set the order of truncation at $\tilde{N} = (20, 20)$, as we have checked the convergence of positive reduced matrix $\rho(\tau)$. This method can describe the dynamics of a system with a nonperturbative and non-markovian system-bath interaction at finite temperature, even under strong time-dependent perturbations. This formalism is valuable because it can be used to study not only strong-bath coupling, but also quantum coherence or quantum entanglement. The information concerning the system-bath coherence is stored in the hierarchical elements, which allows us to simulate the quantum entangled dynamics between the system and the environment. In the particular case of this manuscript, we shall focus on the entangled dynamics of a driven bipartite system and its environment.

II. ENVIRONMENTALLY INDUCED DYNAMICS ON MAXIMALLY ENTANGLED BIPARTITE STATES

For the particular purpose of this work, we shall consider entangled two-qubits states within the class of $X$-states, defined in the computational standard basis $B = \{|1 \equiv |11 \rangle, |2 \equiv |10 \rangle, |3 \equiv |01 \rangle, |4 \equiv |00 \rangle\}[6]$. 

$$\rho_X = \begin{pmatrix} \rho_{11} & 0 & 0 & \rho_{14} \\ 0 & \rho_{22} & \rho_{23} & 0 \\ 0 & \rho_{32} & \rho_{33} & 0 \\ \rho_{41} & 0 & 0 & \rho_{44} \end{pmatrix}.$$  

(10)
This type of matrices are commonly used in a variety of physical situations. For several physical dynamics this structure is further maintained in time. These X states contain the Werner-like states defined as
\[ \rho_r(0) = \frac{1-r}{4} \mathbb{1} + r|\tilde{\phi}\rangle\langle \tilde{\phi} | \]
where \( r \in (0, 1) \) determines the mixing of the state and \( \mathbb{1} \) is the unit matrix in the Hilbert space \( 4 \times 4 \). The state \( |\tilde{\phi}\rangle \) may be any of the following states:
\[ |\Phi_{\pm}\rangle = \sqrt{1-p}|01\rangle \pm \sqrt{p}|10\rangle, \quad (12) \]
\[ |\Psi_{\pm}\rangle = \sqrt{1-p}|00\rangle \pm \sqrt{p}|11\rangle, \quad (13) \]
where \( p \) determines the degree of entanglement, being \( |0\rangle \) and \( |1\rangle \) eigenstates of the Pauli operator \( \sigma_z \). It is easy to note that when \( p = 1/2 \), the above states are the Bell states. For \( r = 0 \) the Werner-like states become totally mixed states, while for \( r = 1 \) they reduce to the Bell states in Eqs. (12) and (13). There are two subclasses, namely states that are diagonal on a subspace of single excitations and states that are diagonal in the subspace of zero and two excitations. In the following, we shall consider an initial bipartite state of each of the two subclasses and study the Concurrence as it evolves in time and driving is included in the system. It is important to recall that we shall work with dimensionless frequencies and temporal parameter \( \tau \), say \( \Omega_s = \Omega_i/\lambda, \Delta_i = \Delta_k/\lambda, \omega_D = \omega_D^i/\lambda \). We shall assume a bath correlation time \( \tau_c = 1 \).

### A. Initial maximally entangled states \( |\Phi_{\pm}\rangle \)

In this subsection, we shall focus on the main features of the driven non-interacting qubits when embedded in a common structured environment. We shall consider only one excitation is present in the system and the environment is initially in vacuum. This means that at \( t = 0 \), the cavity is initially in a vacuum state \( |0_k\rangle \). We consider the initial state as
\[ |\Phi_{+}\rangle = (\sqrt{1-p}|01\rangle + \sqrt{p}|10\rangle) \otimes_k |0_k\rangle \quad (14) \]
which means by defining the initial density matrix in Eq. (11) with \( r = 1 \) and \( |\tilde{\phi}\rangle = |\Phi_{+}\rangle \). The reduced density matrix takes the form
\[ \rho(t) = \begin{pmatrix} 0 & 0 & 0 & 0 \\
0 & \rho_{22}(t) & \rho_{23}(t) & 0 \\
0 & \rho_{23}^*(t) & \rho_{33}(t) & 0 \\
0 & 0 & 0 & 1 - \rho_{22}(t) - \rho_{33}(t) \end{pmatrix}. \quad (15) \]

We can start by studying the loss of Purity as time evolves in the case of an initial maximally entangled state (MES), say \( p = 1/2 \). The dynamics of the system is determined by the coupling between the system and the environment. It is commonly found in the Literature, the definition of bad and good cavity determined by the value of the factor \( R = \gamma_0/\lambda \). This means that for a weak coupling, we have \( \gamma_0 < \lambda \), leading to a \( R < 1 \), commonly known as bad cavity limit. Otherwise, for a stronger coupling, \( R > 1 \) yields a good cavity limit. We shall use this convention to characterize the strength of the coupling. These qualitatively different behaviors are shown with solid lines in Figure 1.

\[ \text{FIG. 1: (Color online) We show the degradation of Purity of the bipartite system as time evolves (measured in natural cycles \( N = \pi/\tau_s \) for different couplings to the environment. Solid lines represent the same value for the system parameters (\( \Omega_s = 10, \Omega_2 = 15 \)) but different strength couplings \( R \). For these values we have \( \tau_s \sim \tau_c \). The dashed line is a representative value for \( \tau_s < \tau_c \) (\( \Omega_s = 10, \Omega_2 = 20 \)), with a strong environment \( R = 1 \). Finally, the dot-dashed line is a representative situation for \( \tau_s > \tau_c \), for a near-resonance situation with \( R = 1: \Omega_s = 10, \Omega_2 = 11 \). As it can be seen, a stronger coupling to the environment leads to a bigger loss of Purity (\( R = 5 \)). As \( \tau_c \) represents proper times, it indicates different timescales in the diverse situations (\( N=15 \) for the dashed line represents a shorter time than for the others). All parameters are dimensionless (\( \Omega_s/\lambda, \Delta_i/\lambda, \tau_s = 1, R = \gamma_0/\lambda, J = 0 \)). No driven is considered.} \]

Therein, we can see that by changing the value of the coupling constant \( \gamma_0 \), we can simulate different cavities behaviors (leaving \( \lambda \) fixed). For strong coupling we can see the evolution is accompanied by the typical fast oscillations of non-markovian evolutions (solid lines for \( R = 1 \) and \( R = 5 \)). In Figure 1, we have also included weak coupling (\( R = 0.01 \) and \( R = 0.1 \)) for the same dynamical timescale \( \omega_s = \omega_2 - \omega_1 \) and \( \tau_s = 2\pi/\omega_s \). Further, we have added two other representative situations for a strong coupling \( R = 1 \). The dot-dashed line is for a quasi-resonant case, meaning both particles have very similar frequencies. This yields \( \tau_s > \tau_c \). On the contrary, the dashed line is for two considerably different atom frequencies with \( \tau_s < \tau_c \). As \( N \) indicates the number of natural cycles elapsed, then it is instructive to recall that it represents longer times for longer \( \tau_s \). We can note that the loss of Purity is done in a few natural cy-
cles in the near-resonance case, for a strong environment \( R = 1 \) (even faster than for the case \( R = 5 \) and \( \tau_s \sim \tau_c \)). This means that, depending on the system’s timescale, the transition between atomic states has already been achieved for \( N = 15 \), leading to an increment in the population of \( |00\rangle \) state (\( \rho_{00}(t) = 1 - \rho_{22}(t) - \rho_{33}(t) \), see Eq.(15)), and therefore of Purity (see appendix Section A). Likewise, for a shorter \( \tau_s \), it seems that a stationary state has not already been achieved. The advantage of this numerical method is that by choosing the right set of parameters, we can simulate a different type of environment and obtain the corresponding dynamics beyond the rotating-wave approximation.

In the following, we shall focus on how external driving can affect (or enhance) the entanglement dynamics under a strong regime \( R = 1 \). We shall consider the qubits to have similar (but not equal) frequencies yielding \( \bar{\tau}_s \sim \tau_c \). In particular, we shall investigate to what extent external driving acting solely on the bipartite system can preserve quantum correlations in a strong regime where memory effects of the environment take place. The dynamics of the bipartite two-level driven system comprises three different dynamical effects, each occurring on a different timescale. Dissipation and decoherence occur on the relaxation timescale \( \tau_r \) and non-Markovian memory effects occur for times shorter than or similar to the reservoir correlation timescale \( \tau_c \) [12] (in addition to the system’s timescale \( \tau_s \)).

Quantum decoherence implies a rapid reduction of the off-diagonal terms of the bipartite reduced density matrix. The quantity for measuring the entanglement between the different parts of the composite system is the Concurrence [2, 6]. The Concurrence for the evolution of this state can be computed as \( C(\rho_r) = \max(0, \sqrt{\lambda_1} - \sqrt{\lambda_2} - \sqrt{\lambda_3} - \sqrt{\lambda_4}) \), where \( \lambda_1, \lambda_2, \lambda_3 \) and \( \lambda_4 \) are the eigenvalues of \( \rho_r = \rho_c (\sigma_y^1 \otimes \sigma_y^2) \rho_c^* (\sigma_y^1 \otimes \sigma_y^2) \). We start by adding driving to only one of the particles, assuming similar frequencies \( \Omega_i \) and different detuning ones \( \Delta_i \). In Figure 2, we show the behavior of the Concurrence as time evolves for different driving situations. In the top panel of Figure 2 we add driving to one of the particles, say particle number 1. Then, \( \omega_1(t) = \Omega_1 + \Delta_1 \cos(\omega_1^D t + \varphi_1) \), and leave the other particle undriven \( \omega_2 = \Omega_2 \). We can see the behavior is qualitatively different as the driving frequency varies. The blue solid line is for \( \omega_1^D = 0 \), which means no driving at all, and can be used as a reference for the undriven case. The light blue dashed line is for \( \omega_1^D = 0.1 \) and the purple dotted-dashed line for \( \omega_1^D = 1 \). The magenta dashed line represents \( \omega_1^D = 2 \) and the gray dotted line \( \omega_1^D = 4 \) (all frequencies have been adimensionalized by \( \omega_D = \omega_1^D / \lambda \)). We can even note that for \( \omega_1^D = 2 \) and \( \omega_1^D = 4 \) there is entanglement sudden death (ESD) occurring at different times, while for \( \omega_1^D = 1 \), Concurrence is enhanced when compared to the static situation.

We can also study the behavior of Concurrence as the driven particle is number 2 with \( \omega_2 = \Omega_2 + \Delta_2 \cos(\omega_2^D t + \varphi_2) \) and number 1 is static (middle panel). The blue solid line is for \( \omega_2^D = 0 \) and light blue solid line for \( \omega_2^D = 0.1 \).

We can see that Concurrence has bigger values at longer times when driven at a small driving frequency (even compared to the specular situation in top panel). The purple dashed line represents \( \omega_2^D = 1 \), the magenta dot-dashed line \( \omega_2^D = 2 \) and the gray dotted line \( \omega_2^D = 4 \).

FIG. 2: (Color online) We show how the external driving on each particle affect the Concurrence of the bipartite initial system as time evolves (measured in natural cycles \( N \)). At the top panel, we add driving frequency to the one of the particles composing the bipartite system (\( \omega_1^D = 0.1 \), \( \omega_2^D = 1 \), \( \omega_1^s = 1 \) and \( \omega_2^s = 2 \)). In the middle panel we add driving to the other \( \omega_1^D = 0.1 \), \( \omega_2^D = 1 \), \( \omega_1^s = 1 \) and \( \omega_2^s = 2 \). Finally, in the bottom panel, we add driving to both particles (\( \omega_1^D = 3 \) and \( \omega_2^D = 1.7 \), \( \omega_1^s = 2 \) and \( \omega_2^s = 3 \) and \( \omega_1^s = 3 \) and \( \omega_2^s = 2 \)). Parameters: \( R = 1 \), \( \tau_c = 1 \), \( \Omega_1 = 15 \), \( \Omega_2 = 10 \), \( \Delta_1 = 1 \), \( \Delta_2 = 7 \), \( \varphi_1 = \pi \), \( \tau_s = 1.04 \), \( J = 0 \).
It is interesting to note the qualitatively different behaviors obtained for similar values in both different panels. Finally, we can add driving to both particles at the same time. The behavior of the Concurrence is shown in the bottom panel for some set of values of $\omega_1^2$, $\omega_2^2$. As can be seen, it is not that easy to predict the behavior of the Concurrence when both particles are driven. However, we can note that for some set of values, Concurrence is enhanced and quantum correlations are evidently preserved over longer times compared to the static case. This result agrees with that found for a single driven atom in [12]. In order to show the full picture, we include all set of values for $\omega_1^2$ and $\omega_2^2$ in Figure 3 (a). Therein, we show how driving on both particles affects the evolution of the initial maximum Concurrence for a strong coupling regime ($R = 1$). On the top left corner, we show the Concurrence for the bipartite system having elapsed one natural cycle, say $N = 1$. As the interaction with the environment is switch on at $t = 0$, Concurrence suffers an abrupt decrease but starts oscillating thereafter. However, the later evolution strongly depends on the external driving, because we can see that we can find areas with greater or lesser degree of entanglement (compared to the static situation) at $N = 3$. There are areas where entanglement has increased compared to the similar static situation where driving is not considered (in the bottom left corner). This fact is accentuated for later times as can be observed for $N = 5$. Black areas show that entanglement has been abruptly destroyed in agreement with Figure 2, bottom panel. Concurrence for $N = 7$ is shown in the right bottom picture. Therein, we can see that Concurrence is generally destroyed for this timescale in the strong coupling regime for this initial bipartite state.

![Figure 3](image_url)

**FIG. 3:** (Color online) (a) We show how the external driving on each particle affects the Concurrence of the maximally entangled initial state of the bipartite system for different times (measured in natural cycles $N$) for different detuning frequencies and strong coupling. Parameters used: $R = 1$, $\tau = 1$, $\tau_s = 1.04$, $\Omega_1 = 15$, $\Omega_2 = 10$, $\Delta_1 = 4$, $\Delta_2 = 7$, $\varphi_1 = \pi$ and $J = 0$. (b) Concurrence of the bipartite initial system for different times ($N$) for similar detuning frequencies under strong coupling. Parameters used: $R = 1$, $\tau_c = 1$, $\tau_s = 1.03$, $\Omega_1 = 15 = \Omega_2$, $\Delta_1 = 3$, $\Delta_2 = 3.1$, $\varphi_1 = \pi$, and $J = 0$.

We can try to understand the results by assuming they depend on the form of the external driving we are introducing as it moulds the response of the bipartite system against the environment. By looking at the figure, it seems that higher frequencies imply a constant flux of driving which in turn can be associated with a stronger Concurrence for the initial MES state. On the contrary, if the driving has a spaced effect in time, its competition against the memory effects of the bath is weak and it may result in a lesser degree of entanglement as time evolves. It is important to recall that in Figure 3(a), $\Delta_1 < \Delta_2$ and this fact can lead to biased conclusions. Hence, in order to see to what extent our results depend on the value of the detuning frequency, we shall next consider the evolution in time of an initial maximally entangled state $|\Phi_+\rangle$, under similar detuning frequencies leading to a quasi-resonant condition. Then, we shall drive the system with $\Delta_1 \sim \Delta_2$, leaving fixed $\tau_s \sim \tau_c$ for a proper comparison. In Figure 3(b) we can observe the corresponding panels for the time evolution of the Concurrence ($N = 1$, $N = 3$, $N = 5$ and $N = 7$). In this case, patterns seem to be symmetric and quantum correlations seem to prevail for longer times. In $N = 5$ there are less regions of null Concurrence than in the corresponding
previous case. In this case, when frequencies are similar, beats take place and their periods are longer, which seems to enhance quantum correlations. For \( N = 7 \) we can find clean areas where quantum correlations are still alive and of greater strength when compared to the corresponding panel of Figure 3(a).

So far, we have seen that having a highly detuned scenario does not necessarily enhance quantum correlations (Figure 3.(a)). We can see that they disappear soon enough, in some areas even earlier than for the undriven case (left corner of the plots). We believe the non-Markovian environment rules the evolution of the system in this particular case. However, when the system has similar detuning frequencies \( \Delta_1 \) (Figure 3.(b)), the dynamics is considerably different, exhibiting regions where quantum correlations are preserved longer compared to the static case. We can interpret this result by considering the unitary phase factor \( e^{-i \int_0^{\tau_s} (\omega_1(t') - \omega_i(t')) dt'} \) in the case \( \Delta_1 \sim \Delta_2 \). In such a situation, the phase factor can be approximated by \( (\Omega_2 - \Omega_1) \tau_s + \Delta/\omega_D \sin(\omega_D' \tau_s) \).

We must note that we have further considered \( \tau_s \sim 1 \). This means that driving is the resultant of some other periodic function of period \( T_R = 2\pi/\omega_D' \). This would be equivalent to having a particle of renormalized frequency \( \Omega_2 - \Omega_1 \) to which driving is added. We can interpret the results obtained for this situation by comparing to those obtained for a driven two-level particle in the presence of a structured environment. In [26], authors have studied to what extent the effect of adding driving on the system can increase the non-Markovianity (NM) with respect to the undriven case. They have shown that driving can not increase the degree of NM for strong couplings. Further, authors have shown that there is a large area where NM is suppressed in intermediate couplings (\( \gamma_0 \sim \lambda \), herein \( R = 1 \)) for \( \omega_D/\Delta \sim 1 \). It has later been shown that this suppression of NM can have further detectable effects as for example in the geometric phase acquired by a two-level system evolving coupled to a strong environment. It has been evidenced that, when \( \gamma_0 \sim \lambda \), a two-level driven evolution with \( \omega_D/\Delta \sim 1 \), verifies the suppression of revivals and ensures a smooth evolution, allowing an acquisition of a geometric phase more similar to the unitary one [12]. Therefore, we believe that this reported suppression of NM can be responsible for a preservation of quantum correlations as can be seen in the upper corner of Figure 3.(b) where \( \omega_D/\Delta \sim 1 \).

A very interesting result reported in [7, 11], is the steady-state entanglement. It is easy to prove that \( |\Phi_+\rangle \) is an eigenstate of \( H_S \) and \( H_I \) for the particular situation that \( \omega_1 = \omega_2 \) and \( J = 0 \). In Figure 4 we show the evolution of Concurrence for different initial maximally entangled states, \( |\Phi_{\pm}\rangle \), in and out of resonance (\( \Omega_1 = \Omega_2 \) and \( \Omega_1 \neq \Omega_2 \) correspondingly, \( \Delta_1 = 0 \)). The black dotted line corresponds to the resonant case of \( |\Phi_{-}\rangle \), while the magenta dashed line is the off-resonant case, for \( \tau_s \sim \tau_c \).

The dark gray solid line represents the off-resonant case for \( |\Phi_{+}\rangle \), while the blue dot-dashed line is the resonant case of the same initial MES [18]. As it can be noted in the figure, Concurrence is enhanced for the initial \( |\Phi_{-}\rangle \) state (with respect to \( |\Phi_{+}\rangle \)) given the same parameters of the system and when driving is not considered at all. Therefore, in the following, we shall explore the effect on quantum correlations of adding driving to the initial MES given by \( |\Phi_{-}\rangle \) under a strong coupling.

In Figure 5 we show the Concurrence for different times elapsed when the maximally entangled state evolves under a structured environment in a strong regime and \( \Delta_1 < \Delta_2 \). We show different time pictures so as to compare with the Concurrence’s time evolution of the initial \( |\Phi_{+}\rangle \) state. On the left top row we include \( N = 1 \) on the left and \( N = 3 \) on the right, while in the bottom right we present \( N = 5 \) on the left and \( N = 7 \) on the right. Similarly, in Figure 5(b) we include the Concurrence for different times elapsed when the maximally entangled state evolves under a structured environment in a strong regime when the system is driven with similar detuning frequencies, assuming \( \tau_s \sim \tau_c \). On the left top row we include \( N = 1 \) on the left and \( N = 3 \) on the right, while in the bottom right we present \( N = 5 \) on the left and \( N = 7 \) on the right for the correct comparison among the different initial conditions.
When comparing results obtained in Figure 3 and Figure 5, we can note that similar detuning frequencies exhibits stronger quantum correlation at longer times. Among both cases, we can observe that when the initial MES is $|\Phi_-\rangle$ (Figure 5 (b)), quantum correlations seem to prevail for more set of parameters than when the initial MES is $|\Phi_+\rangle$ (Figure 3 (b)). In the particular case of $|\Phi_-\rangle$, for the same timescale, quantum correlations seem to be stronger for some particular values verifying $\omega_D/\Delta \approx 1$. As in the above figures, the detuning frequencies have been kept fixed, we shall further explore other different driving situations for the initial state $|\Phi_-\rangle$, allowing for the existence of interaction among the particles through the parameter $J$ as well. In Figure 6, we show a dotted black line for the resonant undriven case $\Omega_1 = \Omega_2$ as a reference. The blue solid case is for a driven situation of a higher frequency $\omega_D^1 = 7 = \omega_D^2$, than the dot-dashed purple line ($\omega_D^1 = 3 = \omega_D^2$), both lines for $\Delta_1 = 1, \varphi_1 = \pi$ and $\Delta_2 = 1.1$. We can see that these lines correspond to a near-resonance condition since frequencies are very similar. In this particular case, it is important to note that Concurrence has a small decrease in comparison to the static case. The green dotted line corresponds to a smaller difference among frequencies, a nearer-resonance situation. The orange dashed line represents other values of detuning frequencies and driving: $\Delta_1 = 2, \Delta_2 = 5, \varphi_1 = 0$ and $\omega_D^1 = 3$ (still small but bigger difference than the other cases). These values can be well compared to the situation when $\Delta_1$ and $\Delta_2$ are bigger, leading to a greater difference $\omega_2(t) - \omega_1(t)$. The dashed magenta line is for $\Delta_1 = 5, \varphi_1 = \pi, \Delta_2 = 5.1$ and $\omega_D^1 = 8$. The gray solid line is for $\Delta_1 < \Delta_2$, as the driving situations shown in Figure 5(a). These representative values show that a small difference among
consider \( \Omega \) as function of \( J \), the resonance. In order to exemplify this statement we have initially MES \(|\Phi_-\rangle\) for different values of \( \Delta_1, \Delta_2, \omega_D \), and \( \omega_D^2 \).

The top dotted black line represents the undriven case with \( \Omega_1 = \Omega_2 = 15 \). The dotted-dashed green line on top represents a quasi resonant case since \( \Omega_1 = 15 = \Omega_2 \) and \( \Delta_1 = 0.5, \Delta_2 = 0.5, \varphi_1 = \pi, \) very similar frequencies. The top blue solid line corresponds to \( \Delta_1 = 1., \Delta_2 = 1.1, \varphi_1 = \pi \) and \( \omega_D^{(2)} = 7 \), while the purple dot-dashed line differs in the driving frequency \( \omega_D^{(2)} = 3 \). The dashed orange line is for \( \Delta_1 = 2., \Delta_2 = 5, \varphi_1 = 0 \) and \( \omega_D^{(2)} = 3 \). The magenta dot-dashed line represents the evolution of \( \Delta_1 = 5., \Delta_2 = 5.1, \varphi_1 = \pi \) and \( \omega_D^{(2)} = 8 \). The gray solid line is for \( \Delta_1 = 4, \Delta_2 = 7, \varphi_1 = \pi, \omega_D^{(2)} = 5 \).

The brown dotted line has similar values than the blue solid line but for \( J = 1 \). Parameters of the environment: \( R = 1, \tau_c = 1 \).

In Figure 7, we have set \( \omega_D^{(1)} = \omega_B = \omega_D \). We can note that, in the case of equal frequencies \( \omega_1 = \omega_2 = \omega \), \( H_s(\Phi_-) = -\frac{J_2}{\sqrt{2}} |\Phi_-\rangle \). As in that figure we have considered \( \Omega_1 = \Omega_2 \) and \( \Delta_1 \approx \Delta_2 \), it is easy to see that if \( J \sim \omega_D \), we can assume the system is near another resonance. In order to exemplify this statement we have included in Figure 8, the behaviour for the Concurrence as function of \( J \) and \( \omega_D^{(1)} \), but setting \( \omega_B = 1 \) for \( N = 2 \). Likewise, we can see that Concurrence has bigger values for larger values of \( J \) for an equal time comparison.

In this Section, we have shown that adding driving frequencies to two particles embedded in a structured environment can sometimes preserve quantum correlations. By comparing both initial bipartite states \(|\Phi_+\rangle\) and \(|\Phi_-\rangle\), we have seen that in both cases quantum correlations are better preserved for similar detuning frequencies rather than in a highly detuned scenario. In the case of an initial MES \(|\Phi_-\rangle\) state, due to the particular characteristics mentioned above, we have further seen that quantum correlations are better preserved when the initial state is driven to a quasi resonant case. In addition, we have also shown that Concurrence become less robust as we get apart from the resonance condition. In those cases, the relation between \( \Delta/\omega_D \) becomes important if the detuning frequencies are similar. Further, having an extra source of entanglement such as the transverse coupling considered herein, seems to enhance quantum correlations for this particular state. All in all, the quasi resonant case with initial bipartite state \(|\Phi_-\rangle\) seems a particular scenario where driving can help to preserve quantum correlations.

**B. Initial maximally entangled states \(|\Psi_\pm\rangle\)**

Let us now consider the case of two excitations initially present in the system. In this case, we can con-
FIG. 8: (Color online) Concurrence as time evolves for an initially MES $|\Phi_-\rangle$ driven to a quasi-resonant case, for different values of $\omega_D^R$ and $J$ (by setting $\omega_D^R = 1$) and $N = 2$. Parameters used: $R = 1$, $\tau_c = 1$, $\Omega_1 = 15 = \Omega_2$, $\Delta_1 = 1$, $\Delta_2 = 1.1$, $\varphi_1 = \pi$.

We consider the initial state limited to the subspace spanned by $\{|00\rangle, |11\rangle\}$, represented by $|\Psi_\pm\rangle$ of Eq. (13) [21]. As we have seen in the above section, there are some situations in which quantum correlations can be preserved. If this also happens for initial states $|\Psi_\pm\rangle$, we can search for further consequences as for example the acquisition of a geometric phase. The advantage of studying the dynamics of this maximally entangled state under the action of a strong environment is that it can be compared to some known results obtained for a purely dephasing model, say the model presented in this manuscript and compare to the results of a dephasing model presented in [13]. In particular, Purity is enhanced by the inclusion of a transverse coupling (red dotted lines in Figure 9) among the particles (in addition to driving) in the dipolar coupling. In the following, we shall further focus on another interesting feature of bipartite system.

FIG. 9: (Color online) Degradation of Purity for different coupling strength in both comparative models: solid lines represent the potential proportional to $\sigma_x$ while non-solid lines labeled with $V_z$ correspond to a purely dephasing model for weak $R = 0.1$ and strong coupling $R = 1$. For strong coupling $R = 1$, we have further compared the loss of Purity for a static $\omega_D^{1,2}_R = 0$ (black and blue lines) and non static situation $\omega_D^{1,2}_R \neq 0$ (gray line for $\Delta_1 = 0.3$, $\Delta_2 = 0.3$, $\varphi_1 = \pi$, $\omega_D^{1,2} = 7$ while the pink line for $\Delta_1 = 0.4$, $\Delta_2 = 0.6$, $\varphi_1 = \pi$, $\omega_D^{1,2} = 3$) when comparing both interaction models. We have further added $J = 1$ to the driven representative values for the $V_z$ model in the dotted red line and $J = 10$ for the green dotted line on top. The orange solid and yellow dashed lines on top are curves for the undriven situation with $R = 0.1$ for both models. Parameters $R = 1$, $\tau_c = 1$, $\Omega_1 = \Omega_2 = 10$.

It is well known that a MES state acquires a geometric phase of value $\pi$ (or 0) and 0 for a separable state [22]. For this reason, the term topological phase is generally used for the specific case of geometric phases acquired by maximally entangled states. The understanding of geometric phases (GPs) for entangled states is particularly relevant due to potential applications in holonomic quantum computation with spin systems, which provide a plausible design of a solid-state quantum computer. The effect of the environment on a bipartite two-level system coupled to an external environment (bosonic or spin bath) was reported in [13, 23]. In particular, the GP correction for certain maximally entangled states was shown to be null. That is, the phase is built as for unitary evolutions, as a stepwise behavior in steps of $\pi$. The study for a dephasing model was extended to two-qudit in [14]. In this framework, we shall inquire into the role of driving in preserving the geometric phase (or not) for the model presented in this manuscript and compare to the results of a dephasing model presented in [13].

A proper generalization of the geometric phase for unitary evolution to a non unitary evolution is crucial for practical implementations of geometric quantum computation. In [24], a quantum kinematic approach was proposed and the geometric phase (GP) for a mixed state
under non-unitary evolution has been defined as

\[
\Phi = \arg \left\{ \sum_k \sqrt{\varepsilon_k(0)} \varepsilon_k(t) \langle \Psi_k(0) | \Psi_k(t) \rangle \right\} \times e^{-\int_0^\tau dt \langle \dot{\Psi}_k | \dot{\Psi}_k \rangle},
\]

where \( \varepsilon_k(t) \) are the eigenvalues and \( |\Psi_k\rangle \) the eigenstates of the reduced density matrix \( \rho_e \) (obtained after tracing over the reservoir degrees of freedom). In the last definition, \( \tau_s \) denotes a time after the total system completes a cyclic evolution when it is isolated from the environment [21]. We can compute the GP acquired by the bipartite system since we have numerically solved the dynamics of the environment.

When the system is open, the geometric phase that would have been obtained if the system had been closed, \( \Phi_u \), is modified. This means, in a general case, the phase is \( \Phi_g = \Phi_u + \delta \Phi \), where \( \delta \Phi \) is the correction to the unitary phase, induced by the presence of the environment.

![Figure 10](image)

**FIG. 10:** (Color online) Geometric phase acquired by the bipartite state (initially MES) while evolving under different environment parameters. The black asterisk-dotted line is the topological phase acquired by the MES state for a purely dephasing model \( [H_s, H_t] = 0 \), while considering different environments or even driving: it is always \( \pi \). All other lines are for the geometric phase of the MES state for the dipolar interaction potential \( V \) proportional to \( \sigma_z \) defined in Eq. (2). Both solid lines represent the geometric phase obtained in the static case, say \( \omega_D = 0 \) for \( R = 1 \) and \( R = 0.1 \). Dotted lines with circles and squares represent the driven situations for \( R = 1 \) and \( J = 1 \). In an unitary evolution, this geometric phase has a topological nature, and it has been proved to be robust in open quantum evolution under dephasing models [13, 14]. In this latter case, the geometric phase acquired by the bipartite system is \( \pi \) when the initial state is a maximally entangled. However, when the interaction Hamiltonian is dipolar, the model is not longer a dephasing one and the geometric phase looses this topological nature. Hence, it becomes sensitive to external noise. Another important feature we can note is the fact that the GP for the undriven case under a strong evolution is approximately \( \pi/2 \) and then it evolves acquiring a geometric phase proportional to that value in each cycle (solid lines). In [23] some of us have computed the geometric phase acquired by a two level system under the presence of a composite environment, formed by an external bath and another two level particle. It has been reported that when the initial entanglement among the two spin 1/2 particles was maximal then the geometric phase acquired by one spin 1/2 particle was \( \pi/2 \), differently to the geometric phase acquired by the bipartite system evolving under the presence of the external bath (dephasing model). The effect of a dipolar coupling on the geometric phase can be compared as to the one induced by a composite environment [23]. Further, we can note that the geometric phase acquired for a driven bipartite system is less corrected than for the equivalent undriven situation \( \delta \Phi[\omega_D] < \delta \Phi[\omega_D=0] \): the driving done in a strong regime \( R = 1 \) (dotted lines with squares) renders similar values of the geometric phase acquired in an evolution under a weaker environment \( R = 0.1 \) (undriven evolution purple solid line). This result agrees with a previous one, where it has been reported that some values of driving “preserves” the geometric phase [12]. Finally, we can also analyze the role of the transverse coupling in the geometric phase acquired. In the case of the dephasing model, we can see that adding a transverse coupling destroys the robust condition for long time evolution (gray dashed line with crosses in Figure 10). Initially, we obtain a similar value to the topological one \( \varphi_g(N=1)=\pi \) but at later times, the loss of information towards the environment corrects significantly the topological value obtained when isolated. However, for a dipolar environmental coupling (dotted line with dots), we can note that its effect is different, as it leads to a smaller correction to \( \Phi_g \) even yet when compared to a non-driven evolution under a weaker coupling regime \( R = 0.1 \).

In Figure 11 we can see the geometric phase acquired for the MES under a dipolar coupling for a driven evolution and different values of the dimensionless parame-
Parameter $J$. Therein, we can see a representative undriven situation in a purple solid line for $J = 0$. As it can be seen, when compared to the robust topological GP (black dotted line), it is evident the strong effect of the environment during the evolution (recall that in the case of the dotted black line $\delta \Phi = 0$, since $\Phi_d = \Phi_u$. The greater the deviation from this line, the bigger $\delta \Phi$ for each evolution is). As we increase the value of the transverse coupling we can notice that the correction to the unitary geometric phase decreases even though the system evolves under a strong coupling. All dashed lines represent driven situations for different values of $J$. The two different color are included to identify different detuning situations: orange for $\Delta_1 = -\Delta_2$ and $\Delta_1 = \Delta_2$, such that $\omega_D / \Delta \sim O(1)$. This driving has been shown to suppress non-markovian effects [12, 26]. The contribution of the transverse coupling towards a preservation of the GP is considerable. This situation can be explained by the fact that this parameter contributes to preserving the quantum correlations as can be seen in the bottom panel of Figure 11. As the Purity of the system remains approximately constant, the geometric phase acquired in each cycle is approximately constant as well. We can further notice a gray solid line that represents $J \gg 1$. In that case, Purity is closer to one along the evolution. Initially $(N = 1)$, geometric phase is $\varphi_0 = \pi / 2$ as reported in [23] and continues constant (almost a straight line like the dotted one but with a different rate) during the evolution even though the bipartite is in a non-markovian environment in a strong regime.

III. CONCLUSIONS

In this manuscript we have studied the quantum correlations of a driven bipartite state embedded in a common structured environment for different regimes. We have focused the analysis on maximally entangled states of X-class bipartite state. We have implemented a hierarchy equations numerical method since it can describe the dynamics of the bipartite system with a nonperturbative and non-markovian system-bath interaction at finite temperature, even under strong time-dependent perturbations. This formalism is valuable because it can be used to study not only strong-bath coupling, but also quantum coherence or quantum entanglement. The information concerning the system-bath coherence is stored in the hierarchical elements, which allows us to simulate the quantum entangled dynamics between the system and the environment.

In the case of only one excitation present in the system and in the environment, we have studied the degradation of Purity of the bipartite system for different coupling regimes. We considered two different particles (but similar frequencies) and studied the quantum correlations (measured by the Concurrence) if the particles were driven out and on resonance, so as to established in which case quantum correlations were longer preserved. We showed that an initial MES of the form $|\Phi_\ldots\rangle$ driven to a quasi-resonant situation preserves longer quantum correlations and that this effect could be enhanced by the presence of a transverse coupling among the particles of the bipartite system.

As for the case of zero and two excitations in the system and environment, we further dug into the effect of driving and transverse coupling on the geometric phase.
acquired during the evolution. We have compared the results obtained in the model with those reported in the literature for a simpler model of dephasing. We have shown that the robustness condition of the geometric phase is lost when the interaction potential is dipolar. In the case of the dephasing model, we can see that adding a transverse coupling destroys the robust condition for long time evolutions. However, for a dipolar coupling with the environment, we have noted that its effect is different. The dipolar coupling does not preserve the robustness of the geometric phase even though the initial state is a maximally entangled one. The transverse coupling among the particles composing the bipartite was shown to help extend quantum correlations in time leading to a smaller correction of the unitary geometric phase (even yet when compared to a non-driven evolution under a weaker coupling). A combination of driving and transverse coupling among the particles can help suppress the non markovian effects. The dipolar coupling does not preserve the robustness of the geometric phase even though the initial state is a maximally entangled one. Instead, the environmental induced dynamics modifies coherences and populations of the reduced density matrix leading to a great variation of the GP. However, if we introduce a driving into the bipartite system and a transverse coupling among the two-level particles, we can obtain a constant geometric phase, which is not the topological geometric phase. It rather corresponds to the geometric phase acquired by one particle initially composing a maximal entangled state coupled to a spin boson (dephasing model) when the degrees of freedom of the environment and one of the particles are traced out.

The possibility of exploiting the environment as a resource for control has opened a new door in the manipulation of open quantum systems. The generation and stabilization of entanglement is one of the main challenges for quantum information applications. The model presented in this manuscript can be used to simulate experimental situations such as hybrid quantum classical systems feasible with current technologies. It is important to note that if the noise effects induced in the system are of considerable magnitude, the coherence terms of the quantum system are rapidly destroyed and the GP literally disappears. It has been argued that the observation of GPs should be done for times long enough to obey the adiabatic approximation but short enough to prevent decoherence from deleting all phase information. As the geometric phase accumulates over time, its correction becomes relevant on a relatively short timescale, while the system still preserves purity. All the above considerations lead to a scenario where the geometric phase can still be found and it can help us infer features of the quantum system that otherwise might be hidden to us.

Appendix A: Dynamical evolution for an initial bipartite state $|\Phi_+\rangle$

The dynamics of the bipartite will depend on three ingredients: driving, coupling and dissipation. In the following, we shall define all timescales involved in the evolution of the bipartite state. The bath correlation time is defined as $t_c = \lambda^{-1}$. As Eq. (9) deals with re-scaled quantities, $\tau_s = 1$ for this manuscript. The relaxation timescale is then determined by $\tau_r = \gamma_0^{-1}$. As for the bipartite system itself, in the case of one excitation present in the system, there is a characteristic timescale defined as $\tau_s = 2\pi/(\omega_2 - \omega_1)$, that is the time at which the closed bipartite system will get back to its initial state. For zero or two excitations present in the system, the characteristic time is set as $\tau_s = 2\pi/(\omega_1 + \omega_2)$. Finally, if it were a dephasing model, we could define the characteristic decoherence timescale $\tau_{DP}$, as the estimated time at which the coherences are dynamically suppressed by the presence of the environment. As the model defined herein is not a dephasing one, we can get an insight into the Purity of the bipartite system so as to have an estimation of the degradation of Purity suffered by the interaction with an environment.

Herein, we shall consider a structured environment and have no limitations on the coupling. The factor $R$ is defined as the rate between the coupling strength between the system and the bath $\gamma_0$ and $\lambda$, defined as the broadening of the spectral peak of the environment. Particularly, we are interested on a strong coupling $R = 1$. By assuming $R = 1$, we are implying $\gamma_0 \sim \lambda$, which means that $\tau_r \sim \tau_c$. In such a case, non-Markovian dynamics induced by the reservoir memory (describing the feedback of information and/or energy from the reservoir into the system) becomes important.

In this section, we shall go over on some issues about the dynamical evolution of the bipartite in one-excitation subspace for an initial bipartite state $|\Phi_+\rangle$, having defined a strong coupling with the environment. In Figure 12 we show three different situations: $\tau_s < \tau_c$, $\tau_s \sim \tau_c$ and $\tau_s > \tau_c$ ($\tau_r = 1$). Therein, we can note that if we want to study the effect of driving during the dynamical evolution, it is important to choose the model’s parameters that allow such investigation. In the case of $\tau_s > \tau_c$, the system is near resonance since frequencies are extremely similar. On the contrary, for $\tau_s < \tau_c$ frequencies are very different. The qualitatively different behaviours
at long times must be understood by recalling the fact that $N = \tau / \tau_s$ ($\tau$ the dimensionless time defined in Eq. (9)). As $\tau_s$ varies, time elapsed $\tau$ for $N$ cycles is different for the different set of parameters. This means that, for example at $N = 15$, the bipartite evolution can be found at dissimilar stages of the dynamical evolution for the different representative lines.

In order to explain the qualitatively different behaviors for $\tau_s \sim \tau_c$ and $\tau_s > \tau_c$, we have further included Figure 13 and Figure 14.

In Figure 13 we show the dynamical evolution of the representative matrix elements Eq. (15) for $\tau_s \sim \tau_c$. The dot-dashed purple line represents $\rho_{22}(t)$, the red dashed line $\rho_{11}(t)$ and the blue solid line $\rho_{00}(t) = 1 - \rho_{11}(t) - \rho_{22}(t)$. The orange dotted line represents the real part of the coherences $\rho_{21}(t)$. We can see therein that the asymptotic state is achieved for approximately $N = 100$ and the coherences oscillate for several values of $N$. For the temporal timescales studied in Section II.A, we can note the typical oscillations of the Non-Markovian evolution ruled by a strong interaction. Oppositely, in Figure 14 we show the dynamical evolution of the representative matrix elements Eq. (15) for a quasi-resonant condition, $\tau_s > \tau_c$. We can note that the asymptotic state is reached at a fewer number of $N \sim 10$ and coherences oscillate for only a few cycles. In the inset, we can see another set of parameters, where frequencies are even closer and $\tau_s \gg \tau_c$. Therein, we can see the asymptotic state is reached for $N \simeq 2$ and coherences decay rapidly. In time units, we can see that decoherence process is accelerated near the resonance condition. These numerical results can be understood by the help of some analytical estimations obtained under the rotating wave approximation when considering the resonance case, say $\omega_1 = \omega_2$.

In that case, authors showed that coherences decay with a rate set by the environmental spectral broad $\lambda$ [7].

In our manuscript, we particularly consider the situation where particles have similar (but not equal) fre-
frequencies. Therefore, the model allows to drive the particles in and out resonance and see if there is a particular situation where quantum correlations are enhanced. In order to compare equal-timescale evolutions, we ask for \( \tau_s \sim \tau_c \). Adding driving will necessarily add another timescale to the already complex evolution. Dynamical evolution is different for an initial bipartite state \( |\Phi_\pm\rangle \) near resonance since \( |\Phi_\pm\rangle \) is an eigenstate of both \( H_s \) and \( H_I \) when \( \omega_1 = \omega_2 \) [11].
