Role of Resident Stem Cells in Vessel Formation and Arteriosclerosis

Li Zhang,* Shirin Issa Bhaloo,* Ting Chen, Bin Zhou, Qingbo Xu

Abstract: Vascular, resident stem cells are present in all 3 layers of the vessel wall; they play a role in vascular formation under physiological conditions and in remodeling in pathological situations. Throughout development and adult early life, resident stem cells participate in vessel formation through vasculogenesis and angiogenesis. In adults, the vascular stem cells are mostly quiescent in their niches but can be activated in response to injury and participate in endothelial repair and smooth muscle cell accumulation to form neointima. However, delineation of the nature of these cells and both migration and differentiation processes during physiological angiogenesis and in vascular diseases. This review summarizes the current knowledge on resident stem cells, which has become more defined and refined in vascular biology research, thus contributing to the development of new potential therapeutic strategies to promote endothelial regeneration and ameliorate vascular disease development. Key Words: cell lineage | myocytes, smooth muscle | neointima | stem cells | vascular diseases

During development, blood vessels are usually formed through 2 processes: vasculogenesis and angiogenesis. Vasculogenesis refers to the creation of the primary vascular network, as observed during embryonic development, where the blood vessels are formed de novo from progenitor cells (angioblasts).¹ Angiogenesis consists of the sprouting of new blood vessels from the preexisting vascular networks and can occur at any time throughout an organism’s life. Vascular plasticity, either through vasculogenesis or angiogenesis, contributes to both vascular repair and vascular disease development.² Accumulating studies have revealed that both vasculogenesis and angiogenesis require vascular progenitor cell homing or recruitment, proliferation, and differentiation into endothelial cells (ECs) and smooth muscle cells (SMCs), among other cell types.³ These vascular stem/progenitor cells play a key role in the formation of all types of vessels during development.

In adults, the arterial wall comprises 3 layers: tunica intima, which is the innermost layer consisting of a monolayer of ECs surrounded by a basal lamina and delimited by the internal elastic lamina; tunica media, the middle layer, which comprises predominantly SMCs supported by extracellular matrix proteins (elastic and collagen fibers); the adventitia, which is the external layer of the blood vessel containing a variety of cell types, including fibroblasts, macrophages, adipocytes, and pericytes. During the development of vascular diseases, it is believed that EC dysfunction/death induced by risk factors, for example, smoking and diabetes mellitus, could be an initiator that is followed by infiltration of inflammatory cells and deposition of oxidized lipids.⁴,⁵ In this process, some SMCs in the media can dedifferentiate and migrate into the intima together with inflammatory cells to form neointima.⁶ If the process occurs repeatedly, severe lesions can be developed, which could block the lumen of the vessels. Interestingly, recent studies indicate the presence of stem/progenitor cells in all 3 layers of the vessel wall⁷ (Table 1). Furthermore, these cells are shown to actively participate in endothelial repair/regeneration and in the formation of neointimal lesions, in response to injury.⁸,⁹ Therefore, the present article reviews the current state of research mainly focusing on the role of stem/progenitor cells in vessel formation during the embryonic stage and adult vascular remodeling during disease development, with emphasis on (1) the different origins and development of vascular progenitors during angiogenesis/vasculogenesis, (2) the mechanisms of stem cell differentiation into vascular lineages, and (3) the role of stem/progenitor cells in the pathogenesis of vascular diseases, including arteriosclerosis.

Vascular Stem Cells in Development

Blood vessels arise from endothelial progenitors that share a common origin with hematopoietic precursors. These progenitors coalesce to form a primitive vascular labyrinth containing blood cells, and this primitive endothelial plexus progressively expands into a highly organized vascular network by means of vessel sprouting, pruning, and remodeling. In addition to supplying the developing organs with metabolic substances, blood vessels also provide a source of developmental signals during organogenesis and (later on in life) in tissue repair and regeneration. Vasculogenesis refers to the de novo formation of primitive vascular plexus from mesodermal progenitors, such as angioblasts. The term angioblast was first proposed a century ago by Sabin, who in reference to a group of progenitor cells that form new blood vessels (outermost cells) and red blood cells (within the lumen or central cells). Conventional vasculogenesis is usually restricted to de novo blood vessel formation during embryonic development. After vasculogenesis at the initial stage, further blood vessels are generated through angiogenesis, which refers to the generation of a new blood vessel through sprouting or splitting of preexisting vessels, which is followed subsequently by pruning and remodeling into a functional adult circulatory system.

Multipotent Vascular Stem Cells: Mesoangioblasts

Mesoangioblasts are multipotent progenitors of mesodermal tissues that contribute to both vascular and extravascular mesodermal lineages in development and are marked by high expression of VEGFR2/Flk1 (vascular endothelial growth factor receptor/fetal liver kinases). The mesoangioblasts originate from the dorsal aorta and differentiate into most mesodermal tissues. By quail-chick engrafment experiments, Minasi et al showed that aortic cells differentiate into vascular cells and also into other mesodermal lineages, such as blood, cartilage, bone, smooth, skeletal, and cardiac muscle. These vessel-associated stem cells, the mesoangioblasts, participate in postembryonic development of the mesoderm, representing an important origin of vascular stem cells. Interestingly, some ECs isolated from embryonic vessels can differentiate into beating cardiomyocytes and express cardiac markers both in vivo and in vitro. An elegant in vivo study using replication-defective retroviral infection showed that myogenic cells and ECs are derived from a common somatic precursor that resides in the paraxial mesoderm. In addition to ECs, SMCs of the dorsal aorta share a common clonal origin with skeletal muscle during development. By comparison, coronary artery SMCs share a common origin with cardiomyocytes, both of which are derived from Nkx2.5 progenitors that originate from cardiac mesoderm. Another study using Flk1 lineage tracing showed that Flk1+ cells are progenitors for muscle lineages and hematopoietic and vascular ECs. It remains to be determined whether single Flk1 progenitors give rise to both muscle and vascular lineages for clonal analysis would be crucial. These above-mentioned pioneering studies documented that mesoangioblasts constitute a subset of vascular stem/progenitor cells during development (Figure 1). Furthermore, transplantation of mesoangioblast-like, vessel-associated stem cells corrected the dystrophic phenotype of a dystrophic mice model, morphologically and functionally.

Bipotent Vascular Stem Cells: Hemangioblasts

In early embryonic development, hematopoiesis and vasculogenesis are coupled in the extraembryonic yolk sac, where primitive ECs are closely associated with hematopoietic cell lineages. The observation that hematopoietic cells and angioblasts arise in close proximity has long fuelled speculation that a common precursor, the hemangioblast, may exist as the progenitor for both blood and the vascular system (Figure 1). Using embryonic stem cell–derived embryonic bodies, Choi et al identified a common precursor for hematopoietic and ECs. A subsequent study showed that hemangioblasts are a subpopulation of mesodermal cells that expresses Flk1 and brachyury and whose hematopoietic and vascular commitment is initiated in the primitive streak of the mouse embryo. Through the construction of single cell-resolution fate maps, Vogeli et al confirmed that individual bipotent cells can give rise to both hematopoietic and ECs. However, other studies suggested that the hematopoietic and the EC lineages are independently fated among mesodermal progenitors during gastrulation. Lineage tracing studies and clonal analysis of mouse development revealed that hematopoietic and EC lineages are segregated and independent. The debate over the existence of bipotent hemangioblasts has not been completely resolved, and more advanced genetic lineage tracing methods combined with single cell sequencing technology may help to elucidate this important issue in the future. Irrespective of this controversy, knockout of Flk1 resulted in abnormal blood islands and vasculogenesis, indicating that VEGF signaling governs the differentiation and proliferation of both lineages. An additional study also demonstrated that Flk1 is required for both hematopoietic and EC development.

Smooth Muscle Progenitors

Perivascular mural cells are comprised 2 cell types that are required to stabilize vascular networks: pericytes and SMCs. Pericytes surround smaller caliber vessels whereas vascular SMCs surround larger vessels. Here, we focus on the recent advances in our understanding of the developmental origin of...
organ-specific pericytes and SMCs; and use aorta and heart tissues as examples to introduce the heterogeneity of their developmental origins. We also include in this section discussion of the controversy over whether pericytes can be endogenous multipotent stem cells.

One of the hallmarks of arterial SMCs is the heterogeneity of their embryological origin, which may significantly influence the development of vascular diseases. For example, there are 3 distinct origins for SMCs in different segments of the aorta. The Isl1+ secondary heart field contributes to SMCs of the basal aortic root; Wnt1+ neural crest cells contribute to SMCs of ascending aorta and the aortic arch; Meox1+ cells of paraxial mesoderm contribute to SMCs of the descending aorta. The diversity of the developmental origins may, in part, contribute to the site-specific location of vascular diseases because of different properties of the SMCs in each segment, such as gene expression, protease profiles, and cell signaling pathways. For more detailed information, a recent review on SMC origins and differentiation has been published and is summarized in Figure 2. Interesting functional differences have been detected between SMCs of different embryological origins. For example, when exposed to TGFβ (transforming growth factor-beta) signaling, collagen production is increased in SMCs from neural crest origin, but not from mesodermal zone. Homocysteine, a protein related to cardiovascular disease, has been shown to stimulate proliferation of SMCs from neural crest but not from mesodermal origin. Detailed pathophysiological studies of each segment have identified disparities in atherosclerotic plaque deposition, aortic aneurysm distribution, and vascular calcification. Because of these differences, it is important to dissect the pathophysiological roles of each segmental SMC population, specifically in the development of diseases. Generation of human vascular smooth muscle subtypes, by defined differentiation of human pluripotent stem cells, provides a new in vitro means to model origin-dependent disease susceptibility and to develop bioengineered vascular grafts for regenerative medicine. Improved genetic tools would be valuable to precisely target each segmental SMC subtype to understand their distinct in vivo roles in multiple diseases.

 distinct from large arteries, SMCs in most organs are derived from mesothelial cells that cover visceral organs and tissues. Lineage tracing studies showed that these Wt1+ mesothelial cells are progenitors of SMCs or pericytes in the organs, such as intestine, lung, and heart. In the developing heart, coronary SMCs originate from the proepicardium, a structure

Table 1. Vascular Stem/Progenitor Cells in the Vessel Wall

| Vessel Wall Layer | Nomenclature | Cell Markers | Function | References |
|------------------|--------------|--------------|----------|------------|
| Intima or Neointima | EPCs | CD34+/CD45−/Flk-1+/CD31+/Sca-1+/c-Kit+ | Endothelial cell differentiation; Clonogenic potential | Ingram et al9; Torsney et al10; Naito et al11; Fang et al12; Patel et al13; Green et al14 |
| | SMPCs | Sca-1+/CD34+ | Smooth muscle cell differentiation | Torsney et al10; Tsai et al12 |
| Media | EPCs | Sca-1+/c-Kit+/CD34+ or CD34−/Flk-1+/CD31+ or CD31−/Lin− | Endothelial cell differentiation | Sainz et al16; Zengin et al17; Pasquini et al18 |
| | SMPCs | Sca-1+/CD34+ or CD34− | Smooth muscle cell differentiation | Sainz et al16; Passman et al19; Tang et al20 |
| | MSCs | CD29+/CD44+/CD105+/CD34−/CD45−/Sca-1+ or Sca−1− | Chondrogenic, myogenic, and adipogenic lineage differentiation | Pasquini et al17; Tang et al16; Zaniboni et al18; Evans et al19 |
| | MPCs | CD34+/CD31+/CD45+/CD68+ | Myeloid lineage differentiation | Zengin et al17; Zorzi et al20 |
| Adventitia | EPCs | CD34+/Flk-1+/Sca-1+/c-Kit+ | Endothelial cell differentiation | Torsney et al10; Sawada et al21 |
| | SMPCs | Sca-1+/CD34+/CD45−/Nestin+ | Smooth muscle cell differentiation | Hu et al22; Torsney et al20; Klein et al22; Chen et al23; Wong et al24; Klein et al25; Wu et al26; Shen et al27; Majesky et al28 |
| | MSCs | CD29+/CD44+/CD105+/CD90+/CD45−/CD34+/Sca-1+ or Sca−1−/CD31−/Nestin−/Gil− | Chondrogenic, myogenic and adipogenic lineage differentiation; Clonogenic potential | Hoshino et al29; Campagnolo et al30; Pasquini et al31; Klein et al32 |
| | MPCs | Sca-1+/CD45+/F4/80+/CD115+/CD68+ | Myeloid lineage differentiation | Corselli et al33; Tigges et al34; Klein et al35; Evans et al36; Kramann et al37; Majesky et al38; Torsney et al10; Zorzi et al20; Psaltis et al31; Majesky et al38 |

EPCs indicates endothelial progenitor cells; Flk, fetal liver kinases; MPCs, myeloid progenitor cells, such as monocytes and macrophages; MSC, mesenchymal stem cell; and SMPCs, smooth muscle progenitor cells.
that sits between the atrioventricular groove and the septum transversum. Mesothelial cells migrate from the proepicardium and cover the developing heart to form a single layer of epicardial cells. In response to inducing signals from the underlying myocardium, epicardial cells delaminate from the epicardium and undergo an epithelial-to-mesenchymal transition to form mesenchymal cells. A subset of epicardium-derived cells forms pericytes and SMCs of coronary vessels and also cardiac fibroblasts. The migration and differentiation of epicardial cells to generate SMCs are tightly regulated by several signaling pathways, including TGFβ, retinoic acid, Notch, PDGF (platelet-derived growth factor), FGF (fibroblast growth factor), and Wnt/β-catenin. A recent study shows that these coronary SMCs derive from pericytes, in which Jag1-Notch3 signaling regulates their differentiation. Furthermore, endocardial cells, from the innermost layer of the myocardium, also undergo epithelial-to-mesenchymal transition to form mesenchymal cells, and some of them contribute to pericytes and SMCs. The differentiation of endocardial cells to coronary SMCs requires canonical Wnt signaling involving Frizzled4, β-catenin, and EC-derived Wnt ligands. In the developing heart, endocardial and epicardial progenitors coordinately contribute to the majority of coronary SMCs. Whether adult endocardial or epicardial cells continue to contribute to SMCs under homeostasis or after injury remains largely unexplored.

**Bipotent Progenitors of Endothelial and SMCs**

ECs and SMCs originate from different progenitors in most organs and tissues. However, there are some conditions under which a common progenitor exists for these 2 distinct cell populations. Flk1+ cells derived from embryonic stem cells differentiate into both ECs and mural cells in vitro and in vivo, indicating Flk1+ cells as bipotent vascular progenitors. In mouse tissue, ECs marked by Nfatc1 contribute to both vascular ECs and a subset of pericytes during development, implying a bipotent potential of Nfatc1+ cells for both vascular lineages. In the developing heart, Isl1+ and Flk1+ cardiac stem cells contribute to both ECs and SMCs, in addition to cardiomyocytes. In the developing heart, Gata4+ or Wt1+ epicardial cells also contribute to both coronary ECs and SMCs. In the adult tissue, protein C receptor–expressing cells serve as bipotent endogenous vascular endothelial stem cells that give rise to de novo formation of ECs and pericytes. However, it remains equally possible that ECs from protein C receptor–expressing cell lineages undergo endothelial-to-mesenchymal transition and differentiate into SMCs. The bipotency of these cells needs further rigorous investigation with improved technology in the future. Furthermore, the molecular mechanisms that determine the diversification of endothelial and SMC lineages from a bipotent progenitor remain to be elucidated.

**Vascular Resident Stem Cells in Adults**

In 2001, Alessandri et al, by performing an aortic ring assay with human embryonic aortas, showed ex vivo outgrowth of capillary-like structures. Moreover, the cells isolated from these outgrowths were CD34+/CD31− and differentiated in vitro into ECs. This suggests that the vessel wall itself could contain resident vascular progenitor cells. In 2003, Majka et al isolated vascular progenitor cells resident in adult skeletal muscle, which could be engrafted and differentiated into the endothelium and smooth muscle. In the same year, Tintut et al also observed that the artery wall contains cells resembling mesenchymal stem cells (MSCs), with the ability to demonstrate multipotency.

---

**Figure 1. Schematic figure showing mesoangioblast and hemangioblast-derived from mesoderm.** Mesoangioblasts are multipotent and give rise to endothelial cells, cardiac or skeletal muscle, and smooth muscle cells. Hemangioblasts are bipotent and give rise to endothelial cells and hematopoietic cells. aSMA indicates smooth muscle actin-α; smMHC, smooth muscle myosin heavy chain; TNNT, troponin I; TNNT, troponin T; and Ve-cad, VE-cadherin.
in vitro. In 2004, Hu et al. provided the first evidence of vascular progenitor cells resident in the adventitia layer of an adult vessel wall. These adventitial progenitors expressed the markers stem cell antigen-1 (Sca-1), c-Kit, CD34, and Flk1. Among these, the adventitial Sca-1+ cells were able to differentiate in vivo into SMCs and to participate in neointima formation.

Since then, numerous studies have been published proving the presence of vascular progenitor cells resident in the vessel wall as a reservoir for multipotent stem/progenitor cells (Tables 1 and 2). For instance, Ingram et al. showed that endothelial progenitor cells, resident in the intima of umbilical vein and aortic vessels, could contribute to EC formation. MSCs were also detected in the inner surface of human varicose saphenous vein. These cells were able to differentiate in vitro into osteoblasts, chondrocytes, and adipocytes. Also in human saphenous vein, Campagnolo et al. observed the localization of CD34+ cells around the adventitial vasa vasorum that showed clonogenic and multilineage differentiation capacities. Zengin et al. reported that CD34+/CD31+ progenitor cells with the ability to differentiate into mature ECs, hematopoietic cells and macrophages, were present in a region contained between the media and the adventitia of adult human blood vessels. Pasquinielli et al. demonstrated the presence of angiogenic MSCs within the human thoracic aorta. Still in the media layer, Sainz et al. isolated a side population of progenitor cells displaying a Sca-1-/c-Kit-/lin-/CD34-/Flk1- profile, which generated cells with EC and SMC phenotypes that could form vascular-like branching structures. Furthermore, Torsney et al. identified progenitor cells expressing Sca-1, CD34, and c-Kit markers within the neointima and adventitia of human atherosclerotic arteries, suggesting that these cells could be the source of SMCs, ECs, and macrophages that form atherosclerotic lesions. Pericytes, which are normally regarded as mural cells, have also been described to possess multipotent stem/progenitor cell properties although controversy still exists on their distinction from MSCs.

**Resident Endothelial Progenitors**

In the small intestine paradigm, stem cells in the crypt give rise to transient amplifying cells, which proliferate and further differentiate into enterocytes in the villi. Whether there is a similar hierarchy when preexisting ECs generate new ECs during angiogenesis remains poorly understood. Using human umbilical vein ECs and human aortic ECs, Ingram et al. demonstrated that a hierarchy of endothelial progenitor cells can be identified and discriminated by their clonogenic and proliferative potential. By a Hoechst dye exclusion method, stem cells in the luminal surface of pre-existing blood vessels have also been identified as an EC side population. This population is dormant in the steady state but generates a significant number of ECs when transplanted into ischemic regions and restores blood flow of ischemic tissue. The notion of the presence of resident endothelial progenitor cells with clonal proliferative and self-renewal capacities in the endothelium lining of the vessels has been widely discussed by Yoder et al. who have provided solid evidence in their studies. Recent work found that there are actually 3 subpopulations of ECs defined by their expression of CD31, VE-cadherin, Sox18, and Flk1. Lineage tracing studies demonstrated that CD31-/Flk1+ is an endovascular progenitor, CD31+/Flk1+ is transit amplifying, and CD31+/Flk1+ is a differentiated cell population. The stepwise differentiation from endothelial progenitors to transit amplifying to mature ECs is governed by Sox18/SoxF transcriptional regulation. In addition, a single c-Kit+ adult vascular endothelial progenitor cell is capable of undergoing clonal expansion to generate millions of endothelial daughter cells in vitro and functional blood vessels that connect to host circulation. Lineage tracing studies on c-Kit+ cells revealed that a subset of ECs express this stem cell marker (Figure 3). Whether the endogenous c-Kit+ cells are resident vascular progenitors and have the potential to generate new blood vessels after injury remain to be investigated. Given the difficulty from the previous literature cited above to exactly define endothelial progenitors in terms of nomenclature or immunophenotyping, Yoder et al. have provided important guidelines for precise terminology. Notwithstanding, the identification of EC hierarchy shifts our understanding of vascular resident endothelial progenitors and their role in tissue repair and regeneration, opening new avenues for better understanding and improved treatment of cardiovascular diseases.
Sca-1+ Vascular Progenitor Cells

The Sca-1 marker, also known as Ly-6A/E, was originally used to define adult murine hematopoietic stem cells. Under homeostatic conditions, the endothelium of large arteries exhibits little Sca-1 expression. However, in response to injury, the number of Sca-1 cells in the endothelial layer of the aorta increases. In addition, apolipoprotein E-deficient (ApoE−/−) mice, which model atherosclerosis, have elevated numbers of Sca-1 cells in the aortic endothelium. Hu et al demonstrated that adventitia-resident vascular progenitor cells express Sca-1 and that these cells contributed to atherosclerosis via migration and differentiation into SMCs. Among other studies, the work of Yu et al further supported the notion that resident Sca-1+ cells contribute to neointima formation, which may increase plaque burden. Nevertheless, Sca-1+ cells may also harbor a potential for reparative and regenerative processes. The differentiation of Sca-1+ cells into SMCs or ECs may participate in endothelial layer regeneration and promote atherosclerotic plaque stability. Furthermore, this capacity of Sca-1+ cells could find a useful application of in tissue engineering, such as artificial vessel generation.

Mesenchymal Stem Cells

MSCs are a group of multipotent stromal cells that can differentiate into various cell types, including osteoblasts, chondrocytes, and adipocytes. MSCs can be isolated from different tissues, including umbilical cord, bone marrow, and adipose tissue. Their properties vary from tissue to tissue. For instance, cells isolated from adult bone marrow display a stable phenotype, expressing SH2, SH3, CD29, CD44, CD71, CD90, CD106, CD120a, CD124, and many other surface proteins. Understanding the mechanisms driving cell differentiation, migration, mobilization, and homing will contribute to future clinical application of these cells as treatments for vascular diseases. Because of their easy isolation and relative abundance compared with other types of MSCs, adipose tissue stem cells have recently become popular in stem cell research. The stromal vascular fraction can be simply obtained by collagenase digestion of adipose tissue and centrifugation to remove mature adipocytes by flotation. Stem cells isolated from human subcutaneous adipose tissue display a specific phenotype, CD34+, CD13+, CD45-, CD14+, CD144-, and CD31-, and can give rise to adipocytes or ECs in vitro. Adipose-derived stem cells that express Sca-1+, CD34+, CD45+, and CD31+ can differentiate into white adipose tissue in mice. One report also demonstrated that CD34+ adipose-derived MSCs could be maintained for 20 weeks although CD34+ adipose-derived stem cells are more plastic.

Although cell culture provides a good approach for studying differentiation, migration, and proliferation in vitro, it is more relevant to study the adipose-derived stem cells in their biological context in vivo. For example, injection of allogeneic abdominal adipose-derived stem cells, either with or without transfection with plasmid-VEGF165, provided a protective role in a rabbit model of critical hindlimb ischemia. They increased arteriolar density and protected against ischemia-induced muscle lesions. Furthermore, Joe et al purified Lin−/Sca-1+/CD34+ cells from the stromal vascular fraction of white adipose tissue of GFP (green fluorescence protein) mice by fluorescence-activated cell sorter and transplanted them in matrigel into wild-type mice. Adipocyte progenitor cells were able to form mature unilocular and multilocular adipocytes with GFP expression. In other research, Miranville et al reported that CD31+/CD34+ stromal vascular fraction cells can differentiate into ECs that express CD31 and develop vascular structures in Matrigel in response to VEGF. Hence, adipose tissue-derived stem cells may participate in angiogenic processes.

Pericytes as Endogenous Multipotent Stem Cells

Cultured pericytes isolated from distinct tissues can also differentiate into multiple cell types, including osteogenic, chondrogenic, and adipogenic lineages. Hence, perivascular cells, principally pericytes, appear to harbor a reservoir of progenitor cells that are an endogenous source of MSCs. In vivo lineage tracing studies using a PDGFRβ (platelet-derived growth factor receptor-beta)-Cre line showed that the mural cell compartment of the adipose vasculature contains progenitors of white adipocytes. Furthermore, pericytes have also been reported to give rise to follicular dendritic cells and skeletal myocytes. Guimaraes-Camboa et al used inducible Tbx18-CreERT2 line to permanently label pericytes and vascular SMCs of multiple organs in vivo and to follow their fate in aging and injury models. Surprisingly, these labeled pericytes remained as pericytes and did not behave as stem cells by differentiating into other cell lineages, challenging the current view of pericytes as tissue-resident MSCs. There are several possible explanations for these discrepant findings. First, the differentiation potential of transplanted cells can be influenced by ex vivo manipulations and hence may not be equivalent to authentic in vivo tracing studies. Second, the differences in the lineage tracing results observed between previous studies and Evan’s could be because of the constitutive PDGFRβ-Cre line used in the former studies. PDGFRβ could be expressed in multiple cell lineages, rendering its promoter unsuitable for tracking the progeny of pericytes. By comparison, Evan’s Tbx18-CreERT2 lineage tracing marker is inducible during development and the Cre activity is, therefore, more controlled temporarily. Moreover, the discrimination of perivascular cells, such as between pericytes or fibroblasts, can be challenging if the tracing is dependent on a single marker. For example, a subset of fibroblasts expresses PDGFRβ and certain populations of pericytes express PDGFRα. Obviously, the previous studies rely on currently known gene profiles that we understand identify pericytes. With the advent of single cell sequencing and improved genetic lineage tracing technology, a more complete understanding of endogenous perivascular stem cells could be achieved.

Vascular Progenitor Cells in Arteriosclerosis

Arteriosclerosis includes native (spontaneous) atherosclerosis, transplant arteriosclerosis, angioplasty-induced restenosis, and vein graft arteriosclerosis. For atherosclerosis, it is believed that a combination of lipid and flow-mediated endothelial dysfunction/death initiates an inflammatory response followed by SMC migration and proliferation to form neointimal lesions. Consequently, focal atherosclerotic plaques are formed, containing a necrotic core encompassing lipid

Zhang et al Vascular Resident Stem Cells 1613
deposition, SMCs, leukocytes—mainly macrophages—and associated debris. Endothelial dysfunction and inflammation also contribute to the other types of arteriosclerosis. Today, many studies demonstrate that vascular progenitor cells can contribute to either endothelial repair, probably beneficial, or proliferative processes that might increase the severity of the arteriosclerotic lesion. Considering the body of work published in the literature and summarized in Table 1 on the presence of vascular progenitor cells in the vessel wall, these cells are a potential source of ECs and SMCs in the development of arteriosclerosis.

**Effect of Risk Factors for Atherosclerosis on Resident Stem Cells**

Genetic or environmental risk factors that lead to hypertension, hyperlipidemia, hyperglycemia, systemic inflammation, circulation of reactive oxygen species (ROS), among other conditions can cause endothelial injury and dysfunction. Smoking is one of the major causes of cardiovascular disease because it induces hypertension, endothelial dysfunction, leukocyte activation, and generation of ROS, which decrease nitric oxide availability.\(^{145}\) ROS are toxic byproducts that lead to oxidative stress, which can activate important transduction pathways, such as G protein–coupled and growth factor receptors, Notch, and Wnt signaling. As a result, vascular cell, including stem/progenitor cell, migration, proliferation, and differentiation are affected. For example, TGF-β, an SMC differentiation factor, activates Nox4 which produces ROS. These in turn upregulate the expression of serum response factor and hence activate SMC gene transcription.\(^{146}\) ROS also induce MSC proliferation and progenitor migration and proliferation by activating MAPKs (mitogen-activated protein kinase) and PI3K/AKT (phosphatidylinositol-3-kinases/protein kinase B) pathways.\(^{147,148}\) Hypertension also induces oxidative stress on the arterial wall and vascular remodeling. Areas of the vessel with disturbed flow reveal higher ROS accumulation and endothelial turnover that can culminate in lesion formation. Vascular stem cells may be mobilized and undergo differentiation to try to repair the damaged vessel. For instance, Xiao et al\(^{149}\) demonstrated that Sca-1+ progenitor cells could differentiate into endothelial lineage in response to laminar flow or VEGF treatment while the flow stimulation in vitro suppressed smooth muscle lineage differentiation. Similarly, laminar flow increased Flk+ cell proliferation and differentiation toward ECs when compared with static controls.\(^{150}\) Hypertensive vessels possess characteristic intimal thickening and medial hyperplasia, associated with enhanced expression of α-smooth muscle actin. These results suggest that stem/progenitor cell migration, proliferation, and differentiation could be a response to cytokines released by the injured endothelium and the underlying inflammation process. Furthermore, mechanical stretching via PDGFR/Ras/ERK (extracellular signal–regulated kinase) pathway is reported to result in the differentiation of progenitors into SMCs.\(^{151}\) For example, in pulmonary artery hypertension, resident PW1+ progenitor cells undergo proliferation and differentiation into SMCs induced by chronic hypoxia, via CXCR4 (C-X-C chemokine receptor) activation.\(^{152}\) Interestingly, hypoxia promotes the proliferation of resident progenitors in the lung.\(^{153}\) Diabetes mellitus–associated vascular diseases show hypoxic tissue, which may be a stimulus for resident progenitors, but there is also hyperglycemia and oxidative stress, endothelial dysfunction, and vessel wall remodeling. With increased levels of ROS

![Figure 3. Proposed roles for vascular wall resident endothelial progenitors in endothelial generation.](image)
and decreased nitric oxide, progenitor mobilization is hampered, and under hyperglycaemia, glycosylated proteins induce progenitor senescence via activation of AKT/p53/p21. Hence, there may be a stimulus for expansion progenitors that is frustrated by other factors. Diabetes mellitus and obesity are risk factors for atherosclerosis, and obesity-related increased perivascular adipose tissue is increasingly accepted to play an active role in vascular remodeling. Adipocytes secrete adipo- kines and cytokines, which may act not only in an autocrine way but also on resident stem cells in the vessel. Recently, Xie et al. revealed that leptin induces the migration of adventitial-derived Sca-1+ progenitor cells after vessel injury, contributing to neointima lesion formation (Figure 5). However, the effect of leptin and other adipokines on resident vascular progeni- tor cells, particularly in the context of diabetes mellitus or obesity-induced vascular diseases, remains to be fully clarified.

Endothelial Repair and Regeneration

As mentioned above, a key initiating event of arterioscle- rosis is the dysfunction/death of the endothelial layer, with increased permeability and impaired endothelium-mediated vasodilation. Endothelial turnover is an important compensa- tory mechanism but also contributes to endothelial leakiness and dysfunction. ECs in the areas of the artery resistant to atherosclerosis have a lifespan of ≈12 months in rats, whereas cells at lesion-prone sites live for weeks and for even shorter times when animals are aged. A study from our group demonstrated that the numbers of dying/proliferating cells in the aortas of ApoE−/− mice and of wild-type animals were significantly different. Importantly, lesion-prone areas displayed a higher turnover rate of ECs, as indicated by BrdU (bromodeoxyuridine)-positive labeling. However, the endo- thelum covering early lesions was leaky because of lower levels of tight junctions. The question is, whether these highly proliferative, leaky ECs are derived from mature ECs or from a specific population of vascular progenitors (see Figure 3). Interestingly, endothelial progenitors that are resi- dent in the intima and shown to participate in vessel formation have higher proliferative ability and increased expression of matrix metalloproteases and growth factor signaling, all of which would favor their participation in endothelial regeneration. But why do ECs in certain regions display increased turnover and loss of barrier function although exposed to a similar concentration of circulating mediators and blood vessel wall–derived signals? A likely explanation is different flow patterns. Interestingly, a recent report demonstrated that laminar shear stress triggers Dll4-dependent proteolytic activation of Notch1 to reveal the Notch1 transmembrane do- main, the key domain that mediates barrier establishment. Expression of the Notch1 transmembrane domain is sufficient to rescue Notch1 knockout–induced defects in barrier function and does so by catalyzing the formation of a novel recep- tor complex in the plasma membrane containing VE-cadherin, a tight junction component. It seems, therefore, that physi- ological shear stress is a key stimulator for endothelial barrier function, as well as reduced cell turnover. Coinciding with this finding is the earlier report that in vitro laminar shear stress can directly stimulate stem cell differentiation toward ECs in the absence of VEGF, which would favor endothelial repair. In general, several key signaling pathways have been proposed for stem/progenitor cell commitment to endothelial lineage via VEGFR2 activation in a ligand-independent manner. How VEGFR2 can be activated by shear stress without VEGF involvement requires further investigation.

From a different perspective, Toledo-Flores et al. observed that Sca-1+/CD45+ adventitial cells possess proangiogenic capacity and may be the source of the vasa vasorum expansion in atherosclerosis in mice. Although in vitro Sca-1+ cell culture can promote expression of endothelial mark- ers, no data demonstrate endothelial lineage differentiation in vivo. However, Sca1+ progenitors can be forced to differenti- ate into ECs in vitro and in vivo via introduction of the gene ETV2. After ETV2 transduction, Sca-1+ adventitial cells significantly increased expression of early EC genes, including VE-cadherin, Flk1, and Tie2 at the mRNA and protein levels. ETV2 overexpression also induced the downregulation of a panel of SMC and mesenchymal genes through epigenetic regulations, mediated by decreased expression of DNA-modifying enzymes, 10-11 translocation dioxygenases. Adventitial Sca-1+ cells grafted on the adventitial side of wire- injured femoral arteries increased vascular wall hyperplasia compared with ungrafted control arteries. Arteries seeded with ETV2-transduced cells showed, on the contrary, reduced hyperplasia compared with controls. Genetic manipulation of vascular progenitors is, therefore, a promising approach to improve vascular function after endothelial injury.

SMC Accumulation in Neointimal Lesions Derived From Stem Cells

Identification

An important feature of the SMCs is their phenotypic plasticity, which enables them to respond to the changes of the surrounding environment. During vascular development or in response to injury, the medial SMCs adopt a synthetic, prolif- erative, and migratory phenotype that can contribute to intima formation. However, vascular stem/progenitor cells may also have roles in neointimal formation. For instance, Hu et al. revealed that the origin of the SMCs in the neointimal lesion of vessel allografts was not bone marrow progenitor cells but locally derived host cells. These findings were further supported by the work on atherosclerosis. Benton et al. concluded that there is a local vessel wall source of SMCs, and Iwata et al. showed that bone marrow cells contribute to vascular inflammation but do not differentiate into SMCs. A role for adventitial Sca-1+ cells as progenitor cells for resident SMCs was supported by Passman et al., who characterized a sonic hedgehog signaling domain restricted to the adventitial layer of the vessel wall. In sonic hedgehog−/− mice, the num- ber of adventitial Sca-1+ cells was drastically reduced and, in parallel, the number of potential SMC progenitor cells was also decreased. Tsai et al. performed a study aimed at ex- ploring the contribution of stem/progenitor cells to neointima formation in decellularized vessel grafts in a mouse model. A decellularized vessel was grafted in the mouse carotid ar-tery, and a neointimal lesion was formed. The lesion exhibited Sca-1+, c-Kit+, and CD34+ cells, with multilineage differen- tiation capacity. After femoral artery injury, a recent report
concluded that >50% of neointimal SMCs are derived from adventitial stem/progenitor cells. Moreover, Roostalu et al.\textsuperscript{169} used a double SMC-marker lineage tracing mouse model to provide solid evidence that adventitial cells are the main contributors to neointimal SMCs in severely injured arteries. Furthermore, genetic fate-tracing using Gli1 as a marker indicates that adventitial stem/progenitor-like cells migrate into the media and neointima during athero- and arteriosclerosis in ApoE\textsuperscript{−/−} mice. Hence, adventitial stem cells can be direct contributors to SMC accumulation in many forms of arteriosclerosis (Figure 4).

**Cell Migration**

Perivascular application of GFP-Sca-1\textsuperscript{+} cells to injured arteries significantly enhanced neointimal lesion formation via progenitor migration.\textsuperscript{121} Application of Sca-1\textsuperscript{+} cells to the adventitial side of vessel grafts resulted in enhanced neointimal lesions.\textsuperscript{29} The potential of Sca-1\textsuperscript{+} cells to migrate from the adventitia to the intima was also demonstrated by the work of Wong et al.\textsuperscript{30} using an ex vivo bioreactor system. Adventitial Sca-1\textsuperscript{+} cells were seeded on the outside of a decellularized vessel, and their migration toward the inner side of the vessel was increased in response to sirolimus stimulation.\textsuperscript{30} Another study by Chen et al.\textsuperscript{30} showed that the adventitia of vein grafts, which underwent intense remodeling, displayed a considerable number of Sca-1\textsuperscript{+} progenitor cells near the vasa vasorum. These cells could differentiate in vitro into SMCs and also had the potential to differentiate into adipogenic, osteogenic, and chondrogenic lineages. Furthermore, ex vivo and in vivo experiments demonstrated migration of the Sca-1\textsuperscript{+} cells to the inner side of the vessels, making a significant contribution to the content of neointimal SMCs.\textsuperscript{29} The mechanisms driving stem/progenitor cell migration seem to involve several chemokines and lipoproteins, and great progress toward their understanding has been made recently. Using combined models, Yu et al.\textsuperscript{121} demonstrated that proliferating SMCs can release several chemokines, including CXCL1 (chemokine [C-X-C motif] ligand), CCL2 (chemokine [C-C motif] ligand), and CCL5, which have a role in attracting vascular progenitors. Single cell tracking experiments indicated that these cells migrate directionally and efficiently but not randomly. Interestingly, Sca-1\textsuperscript{+} progenitor cell migration from the adventitia to the neointima was abrogated and neointima formation diminished, in a wire injury model using CCL2\textsuperscript{−/−} mice.\textsuperscript{121} These findings suggest that vascular stem/progenitor cell migration from the adventitia to the neointima can be induced by SMC release of chemokines, which act via CCR2 (C-C chemokine receptor type)/Rac1/p38 and CXCR2/Rac1/p38 signaling pathways (Figure 5).

**Influence of Obesity**

A recent publication reveals an effect of the adipokine, leptin, on Sca-1\textsuperscript{+} progenitor cell migration and neointimal formation.\textsuperscript{155} Leptin induced the migration of Sca-1\textsuperscript{+} progenitor cells in vitro, which was markedly reduced in cells derived from leptin
receptor knockout mice. Moreover, transplantation of leptin receptor−/− Sca-1+ progenitor cells into the adventitial side of injured artery in leptin receptor−/− mice significantly enhanced neointimal formation. Upregulation of leptin levels in both the vessel wall and the circulation, after vessel injury, promoted the migration of Sca-1+ progenitor cells via leptin receptor–dependent STAT3-Rac1/Cdc42-ERK-FAK (focal adhesion kinase) pathways and enhanced neointimal formation (Figure 5).

Hyperlipidemia

Kokkinopoulos et al used single cell RNA sequencing technology on primary adventitial mouse Sca-1+ cells from wild-type and atherosclerotic-prone (ApoE−/−) mice and found that a group of genes controlling cell migration and matrix protein degradation was highly altered. Adventitial progenitors from ApoE−/− mice displayed an augmented migratory potential both in vitro and in vivo. This increased migratory ability was mimicked by lipid loading either by incorporating oxidized low-density lipoprotein or cholesterol to Sca-1+ progenitor cells. Furthermore, lipid loading increased miRNA-29b expression and induced sirtuin-1 and MMP-9 (matrix metalloproteinase) levels to promote cell migration (Figure 5). These results provide mechanisms by which blood cholesterol levels could influence vascular progenitor cell migration, a promising target for the treatment of vascular diseases.

Differentiation Into SMCs

Concerning the mechanisms underlying SMC differentiation, recent studies reveal the involvement of collagen IV, integrins α1, α5, and β1, and PDGF-β receptor pathways. In addition,
that DKK3 can induce the differentiation of Sca-1+ vascular Sca-1+/CD45+ macrophage progenitor cells in the aortic ad- 
ApoE−/− mice fed with high-fat diet through activation of the loss of DKK3 attenuates atherosclerosis development in 
Wang et al174 also demonstrated that DKK3 can stimulate mu-
(activating transcription factor) and Wnt signaling pathways. 
seems to be a potent SMC differentiation factor associated 
and promoting myocardin expression. Cumulatively, DKK3 
expression in the endothelium and muscles,171–174 that is 
important in the differentiation of partially induced pluripo-
tent stem cells. 175 Recently, Cheng et al 176 demonstrated that 
SMC markers during the development affect their behavior 
neural crest cells versus proepicardium. How different ori-
maments, SMCs derived from different regions, for example, 
also be a source of foam cells. Hence, local resident stem/ 
progenitor cells could be a common progenitor for both SMCs and macrophage-derived foam cells.

Summary and Perspectives
Accumulating evidence suggests the presence of stem/pro-
genitor cells in the vessel wall. Several markers were used to 
identify these stem cells, for example, Sca-1, c-Kit, CD34, 
Flk1, Sox, CD124/90, among others, most of which have been 
listed in Table 2. However, there is no unique marker avail-
able to identify vascular stem/progenitor cells. It is also not 
clear whether all types of vascular stem cells are derived from 
the same source during development or whether they alter in 
adults, especially under disease conditions. To answer these 
questions, further investigations would be needed. Single cell 
gene sequencing and cell linear tracing models may be espe-
cially useful to clarify the nature and the contributions of vas-
cular stem/progenitor cells during development and disease 
formation.

Recent reports indicate the presence of stem and progenitor 
cell populations within the endothelial and other layers of the 
vessel wall. Their definitions and functions should be investigat-
ed in detail in the future. For example, nonbone marrow–derived 
c-Kit+ cells may participate in angiogenesis in ischemic heart, as 
identified by cell lineage tracing models,114–116 but it is unknown 
whether vascular resident c-Kit+ cells have the ability to repair or 
regenerate the endothelium of large vessels. Because atheroscle-
rotic plaques occur mainly in medium-to-large arteries, it will be 
crucial to study the role of vascular endothelial stem cells in the 
repair of damaged endothelium in these vessels.

It is well-known that SMCs within vascular lesions con-
sist of heterogeneous populations, reflecting the variable 
phenotypes and functions of these cells.179 During develop-
ment, SMCs derived from different regions, for example, 
neural crest cells versus proepicardium. How different ori-
gins of SMCs during the development affect their behavior 
during the formation of lesions in adults is a worthy question for 
future study. However, SMCs may be able to dedifferen-
tiate or give rise to other cell types, including MSCs.34,180 
A recent report181 demonstrated that SMCs in injury-induced 
neointimal lesions and in atherosclerotic plaques were oligo-
gonadal, having derived from a few expanding cells, which 
could be quiescent SMC progenitors or be able to dedifferen-
tiate into progenitors. We could speculate that lesional SMCs 
comprise all the different stages of differentiation from stem 
cells, hence display a variety of phenotypes (Figure 6). However, further study is needed to answer what propor-
tion of lesional SMCs is derived from stem cells. Further 
research is urgently needed to investigate the mechanisms 
driving the migration, proliferation, and differentiation of 
stem cells during vascular remodeling. The elucidation of 
these mechanisms should provide vital information needed 
for the development of more efficient or novel therapies for 
vascular diseases.

Acknowledgments
We acknowledge Professor Andrew Newby for his valuable input 
on the revision of this manuscript. Figures 2–4 were prepared using Servier Medical Art image bank.
Table 2. Differentiation Potential of Vascular Resident Stem/Progenitor Cells

| Nomenclature | Common Stem Cell Marker | Localization in the Vessel | Differentiation Potential |
|--------------|-------------------------|---------------------------|---------------------------|
| rEPCs        | Sca-1+                  | Media16                  | Endothelial cells         |
