Gutzwiller projection is a way to construct many-body wave functions that could carry topological order or symmetry protected topological (SPT) order. However, an important issue is to determine whether a given Gutzwiller-projected wave functions (GWF) carries a non-trivial SPT order or not, and which SPT order is carried by the wavefunction. In this paper, we numerically study the SPT order in a spin S = 1 GWF on the Kagome lattice. Using the standard Monte Carlo method, we directly confirm that the GWF has (1) gapped bulk with short-range correlations, (2) a trivial topological order via non degenerate ground state, and zero topological entanglement entropy, (3) a non-trivial U(1) × U(1) SPT order via the Hall conductances of the protecting U(1) × U(1) symmetry, (4) symmetry protected gapless boundary. To our knowledge it is the first numerical evidence of continuous symmetry protected topological order in 2D Bosonic lattice systems.

I. INTRODUCTION

Topological order1–3 was introduced to describe exotic quantum phases without symmetry breaking, such as fractional quantum Hall states,4, 5 or spin liquid states.6, 7 Opposite to Landau’s paradigm of symmetry breaking orders,8, 9 topologically ordered phases can not be distinguished by local order parameters. It was shown that different topological orders differ by many-body entanglement.10 From this point of view, long-range entangled states are topologically ordered and are characterized by exotic properties, such as degeneracy of ground states on a torus, fractional excitations, non-zero topological entanglement entropy11, 12. On the other hand, a short range entangled state is trivial and can be adiabatically connected to a direct product state. However, if the system has a symmetry, the phase diagram will be enriched. Even short-range entangled states can belong to different phases, called symmetry protected topological (SPT) phases.13, 14 Haldane phase,15, 16 and topological insulators17–21 are typical examples of phases that contain SPT order. If the symmetry of a bosonic system is described by group G, then a large class of SPT phases in d + 1-dimension can be constructed via group cohomology \( H^{d+1}(G, U(1)) \) or through nonlinear sigma models.22, 23 In 2+1D, many SPT phases can also be understood through Chern-Simons effective theory.24 Similar to quantum Hall states and topological insulators, the boundary of a 2+1D SPT phase must by gapless if the symmetry is not broken. For continuous symmetry groups such as \( U(1) \) or \( SO(3) \), different SPT phases can be distinguished by Hall conductance, which are quantized to 2. We would like to remark that, before the recent studies of symmetry protected short-range entangled states with trivial topological order (i.e. the SPT states), some progresses were made on symmetry enriched long-range entangled states with non-trivial topological order, the so called symmetry enriched topological states29–34 where the “fractionalized representation” of the symmetry, carried by topological excitations and described by Projective Symmetry Group,29–31 played a key role.

Although it is believed that symmetry can enrich quantum phases of matter, it lacks simple lattice models to realize these nontrivial phases in spatial dimension higher than 1+1D. SPT phases for discrete symmetry groups were understood quite well, since the ground state wave functions and exactly solvable models (usually they are complicated and contain many-body interactions) for nontrivial SPT phases can be constructed.35–38 It is more challenging to realize continuous symmetry protected phases. A U(1) symmetry protected nontrivial phase was reported in a continuous bose model,37 and lattice models that may realize continuous (or combined) symmetry protected topological phases were proposed.37–40 In Ref. 38, the authors proposed projective construction of SU(2) or SO(3) SPT states. And lattice model Hamiltonians that may possibly stabilize SPT states are designed recent.39, 40

Using Gutzwiller-projected wave functions (GWF), we can construct different kinds of SPT states. In the present paper, we will numerically study a spin-1 state on the Kagome lattice constructed by Gutzwiller projected Chern Bands, which was firstly proposed in Ref. 37. We will show that this state is a \( U(1) × U(1) \) SPT state, where the two \( U(1) \) groups correspond to \( \sum S_{z,i} \) conservation and \( \sum S_{i} \) conservation, respectively. This SPT state has the following properties: it is gapped without conventional long range spin order; it has unique ground state and zero topological entanglement entropy; it has non-zero spin Hall conductance, the \( U(1) × U(1) \) charge is not fractionalized; the boundary is gapless if the symmetry is reserved but can be gapped out by the perturbations that breaks the symmetry. As a comparison, we also study a \( S = 1 \) chiral spin liquid state41 which are long-range entangled and contain intrinsic topological order, and show that its gapless edge state is robust against symmetry breaking perturbations. These properties of the Gutzwiller wave functions are directly confirmed numerically using the standard Monte Carlo method.

Remarkably, before projection, above two states are
both chiral at mean field level, but after projection the SPT state becomes non-chiral and the chiral spin liquid remains chiral.

The remaining part of this paper is organized as follows. In sections II and III, we briefly review the parton construction of Gutzwiller projected wavefunctions, and introduce their low energy effective field theory under two different approximations. Readers who are only interested in numerical results may go to IV, where we show that the GWF we are studying has (1) gapped short-range correlation in the bulk, (2) zero topological entanglement entropy and unique ground state, (3) non-trivial Hall conductance, (4) symmetry protected gapless boundary. Section V is devoted to a summary.

II. MEAN FIELD THEORY OF PARTON CONSTRUCTION AND ITS EFFECTIVE FIELD THEORY

There are two approximations to calculate the low energy effective theory from the parton construction: the mean field approach and the Gutzwiller projection approach. They represent two different approximations and the Gutzwiller projection approach is a better one. In this section, we will introduce the mean field approach of the parton construction, and the Gutzwiller projection approach will be introduced in section III.

A. Parton construction

We adopt the fermionic representation of $S = 1$ spin operators $\hat{S}_i^a = F_i^a S_i^a F_i$, where $F_i = (f_{i1}, f_{i0}, f_{i-1})^T$ and the spin state is described as $|m\rangle = f_{m}|\text{vac}\rangle$ with $m = 1, 0, -1$. Here a particle number constraint $\hat{N}_i = f_{i1}^\dagger f_{i1} + f_{i0}^\dagger f_{i0} + f_{i-1}^\dagger f_{i-1} = 1$ should be imposed to ensure that the Hilbert space of fermions is the same as that of the spin. Notice that the spin operator is invariant under the following $U(1)$ gauge transformation $F_i \rightarrow F_i e^{i\phi_i}$.

From the fermionic representation of $S = 1$ spin operators, we will consider the following pairing-free mean field Hamiltonian on the Kagome lattice:\textsuperscript{37}

$$H_{\text{mf}} = \sum_{ij} (t_{m,ij} e^{i\hat{a}_{ij}} f_{m,j}^\dagger f_{m,j} + \text{h.c.}) + \sum_i \lambda_i (\hat{N}_i - 1),$$

(1)

where the complex hopping coefficient $t_{m,ij}$ can be considered as Hubbard-Stratonovich fields in path-integral language, and the averaged value $\lambda_i = \lambda$ is the chemical potential. Since the fermionic representation has a $U(1)$ gauge structure, the mean field state suffers from gauge fluctuations. Here $(\hat{a}_{ij}, \lambda_i)$ are the space and time components of the internal $U(1)$ gauge field $\hat{a}_{ij}$, corresponding to the phase fluctuations of $t_{m,ij}$ and the fluctuation of $\lambda$ respectively. We suppose to integrate out $\hat{a}_{ij}$ to project into the physical Hilbert space. In the mean field approximation, $(\hat{a}_{ij}, \lambda_i)$ are not integrated out and will be fixed as $(\hat{a}_{ij}, \lambda_i) = (\hat{a}_{ij}, \lambda)$.

By tuning the phase of $t_{m,ij}$, we can set the Chern number of each species of fermions to be either 1 or -1. For example, if we only consider nearest neighbor hopping and set the phase to be $e^{i\pi/6}$ (see Fig. 1a & c), then the Chern number for the lowest band is ±1. In the following discussion, we will use the notation $[C_m C_0 C_{-1}]$ to denote the mean field state, where the number $C_m = \pm 1$ stands for the Chern number of the $f_m$ species of fermion.

In above mean-field Hamiltonian, the particle numbers of three species of fermions are conserved respectively. This gives rise to three $U(1)$ spin symmetries. However, if the particle number constraint is satisfied strictly, the total charge (namely, the “electric charge”) degrees of freedom will be frozen. As a consequence, there are two independent $U(1)$ symmetries for the spin model, one generated by $\sum_i S_{z,i}$ and another by $\sum_i (S_{z,i})^2$. In other words, the symmetry group for the spin system is $U(1) \times U(1)$. To describe the spin system correctly, we should couple the fermions to the internal gauge field $\hat{a}_{ij}$. In the following we will give the low energy effective field theory
based on the mean field with fluctuating internal gauge fields.

B. Chern-Simons theory and physical response

Under hydrodynamic and mean field approximations, we can introduce three Chern-Simons field $a_m$ to describe the current of the three species of fermions via $J_\mu = \frac{1}{2\pi} \varepsilon^{\mu\nu\lambda} \partial_\nu a_{m\lambda}$. Then the mean field theory can be described by the Chern-Simons Lagrangian

$$\mathcal{L}_{MF} = -\frac{i}{4\pi} \sum_m C_m^{-1} \varepsilon^{\mu\nu\lambda} a_{m\mu} \partial_\nu a_{m\lambda},$$

if we set $\tilde{a}_\mu = \text{const}$.

After including fluctuating internal $U(1)$ gauge field $\tilde{a}_\mu$, we obtain the following low energy effective theory for the spin system

$$\mathcal{L} = -\frac{i}{4\pi} \sum_m C_m^{-1} \varepsilon^{\mu\nu\lambda} a_{m\mu} \partial_\nu a_{m\lambda} + \frac{i}{2\pi} \sum_m \varepsilon^{\mu\nu\lambda} \tilde{a}_\mu \partial_\nu a_{m\lambda},$$

$$= -\frac{i}{4\pi} \varepsilon^{\mu\nu\lambda} \tilde{a}_\mu K \partial_\nu a_{m\lambda}$$

(2)

where $a_\mu = (a_{1\mu} \ a_{0\mu} \ a_{-1\mu} \ \tilde{a}_\mu)^T$ and

$$K = \begin{pmatrix} C_1^{-1} & 0 & 0 & 1 \\ 0 & C_0^{-1} & 0 & 1 \\ 0 & 0 & C_1^{-1} & 1 \\ 1 & 1 & 1 & 0 \end{pmatrix}.$$  

We only kept quadratic terms and dropped the Maxwell terms. Since $\tilde{a}_\mu$ can be considered as a Lagrangian multiplier, we can integrate it first and obtain an effective mutual Chern-Simons action described by a $2 \times 2$ matrix (see Appendix C.2) \[37\].

If $|\det(K)| \neq 1$ (or the signature of $K$ is not zero, the signature of $K$ is the number of its positive eigenvalues minus the number of negative eigenvalues), the state of the spin-1 system represented by $|C_1 C_0 C_{-1}\rangle$ will carry a non-trivial topological order. If $|\det(K)| = 1$ (or the signature of $K$ is zero), the corresponding spin-1 state will have a trivial topological order. But such a state may have a non-trivial SPT order.

To detect the SPT order, we couple the system with a probe fields $A_\mu^s$ (according to some symmetry) via

$$\mathcal{L}_{\text{probe}} = \frac{i}{2\pi} \varepsilon^{\mu\nu\lambda} A_\mu^s Q^T \partial_\nu a_{\lambda},$$

where $Q = ((q_s)^T, 0)^T$, and $q_s$ is the charge carried by the fermions according to the external probe field $A_\mu^s$.

For the field $A_\mu^s$ that couples to the $U(1)$ charge $\sum_i S_i^z$, $q_s = (1, 0, -1)^T$, which gives rise to

$$Q_{S_z} = (1, 0, -1, 0)^T.$$  

For the field $A_\mu^{q_s^2}$ that couples to the $U(1)$ charge $\sum_i (S_i^z)^2$, $q_s = (1, 0, 1)^T$, which gives rise to

$$Q_{S_z^2} = (1, 0, 1, 0)^T.$$  

Integrating out $a_\mu$ we obtain the response theory

$$\mathcal{L}_{\text{res}} = \frac{i}{4\pi} \varepsilon^{\mu\nu\lambda} Q^T K^{-1} Q A_\mu^s \partial_\nu A_{\lambda}^s \tag{3}$$

and three Hall conductances:

$$\sigma_{H}^{S_z} = \frac{1}{2\pi} Q_{S_z}^T K^{-1} Q_{S_z}, \quad \sigma_{H}^{S_z^2} = \frac{1}{2\pi} Q_{S_z^2}^T K^{-1} Q_{S_z^2}, \quad \sigma_{H}^{S_z^2} = \frac{1}{2\pi} Q_{S_z}^T K^{-1} Q_{S_z^2}. \tag{4}$$

If one of the above three Hall conductances is non-zero, then the spin-1 state has a non-trivial $U(1) \times U(1)$ SPT order.

C. Response mean field theory

When the system couples to an external probe field $A_\mu^s$, the mean field theory should be modified accordingly. To get the correct response mean field Hamiltonian, we integrate out the matter field $a_{m\mu}$ to obtain the effective Lagrangian,

$$\mathcal{L}_{\text{eff}}(A, \tilde{a}) = \frac{i}{4\pi} \sum_m C_m \varepsilon^{\mu\nu\lambda} (\tilde{a}_\mu + q_m A_{\mu}^s) \partial_\nu (\tilde{a}_\lambda + q_m A_{\lambda}^s). $$

(5)

The external field $A_\mu^s$ will induce a background internal gauge field $\tilde{a}_\mu$ — the saddle point value of the $\tilde{a}$ field which can be obtained from $J_\mu = \frac{\delta \mathcal{L}_{\text{eff}}(A, \tilde{a})}{\delta a_{m\mu}} = 0$ in a proper gauge choice,

$$\tilde{a}_\mu = -\frac{\sum_m C_m q_m}{\sum_m C_m} A_{\mu}^s. \tag{6}$$

Rewriting $\tilde{a}_\mu = \bar{a}_\mu + \delta \bar{a}_\mu$, then we have,

$$\mathcal{L}_{\text{eff}}(A, \delta \bar{a}) = \frac{i}{4\pi} \sum_m \varepsilon^{\mu\nu\lambda} C_m \left[ q_m^2 A_{\mu}^s \partial_\nu A_{\lambda}^s + \delta \bar{a}_\mu \partial_\nu \delta \bar{a}_\lambda \right], $$

where $q_m = q_m (1 - \sum_{\sigma} \frac{n_{\sigma} C_\sigma}{c_m})$ is the screened charge. Integrating out $\delta \bar{a}_\mu$ we obtain the response Lagrangian and the spin Hall conductance is given by $\sigma_H = \frac{1}{2\pi} \sum_m C_m \delta \bar{a}_m$.

Noticing that the saddle point value $\bar{a}_\mu$ enters the mean field theory, thus the response mean field Hamiltonian with probing field $A^s$ is given as

$$H_{\text{mf}}(A^s, \bar{a}) = \sum_{m, ij} T_{m, ij}^e \bar{a}_{i,j} + i q_m A_{ij}^s f_{m, ij}^1 f_{m, ij} + \text{h.c.} + \sum_i \bar{a}_0 (N_i - 1), \tag{7}$$
where $\bar{a}_\mu$ is a function of $A_\mu^a$ as given in (6). Physical quantities of the spin system can be measured from the Gutzwiller projected ground state of above mean field Hamiltonian.

### III. GUTZWILLER CONSTRUCTION AND EFFECTIVE FIELD THEORY

#### A. Construction of Gutzwiller wave functions

From the fermionic parton representation of $S = 1$ spin operators, one can construct trial spin wavefunctions for interacting spin-1 systems via Gutzwiller projected mean field ground states,

$$|\psi\rangle_{\text{spin}} = P_G|\text{MF}\rangle,$$

where $|\text{MF}\rangle$ is the ground state of the mean field Hamiltonian (1) and the Gutzwiller projection operator $P_G$ means only keeping the components of the mean field state that satisfy the particle number constraint $\hat{N}_i = 1$. Since the mean field state suffers from gauge fluctuations, Gutzwiller projection is a simple way to partially integrate out the gauge fluctuations to obtain trial spin wave functions. For example, in 1D Gutzwiller projected SO(3) symmetric $p$-wave weak pairing states belong to a nontrivial SPT phase—the Haldane phase.\(^{44}\)

Above GWFs have two $U(1)$ spin symmetries, one generated by $\sum_i S_{z,i}$ and another by $\sum_i (S_{z,i})^2$. The projected states could be a topologically ordered state enriched by the $U(1) \times U(1)$ symmetry, or a SPT state protected by the $U(1) \times U(1)$ symmetry.

#### B. Effective theory for projected states

In section II, we have obtained the effective Chern-Simons field theory for the spin system from the mean-field theory, based on hydrodynamical approximation and by dropping higher order terms in $a_\mu$. In this subsection, we will use a different approximation to calculate the effective field theory from Gutzwiller projected states. Here we make much less approximations except assuming that the GWFs can approach very close to the true ground states. We will show that the two approximations produce the same result.

Gutzwiller projection is equivalent to integrating out the temporal component of the internal gauge field, which result in $\delta(\sum_m f_m^+ f_m - 1)$. However, the spatial component of the internal gauge fluctuations are not completely “integrated out”. Thus, the gauge twisted boundary angles $\theta = (\theta_x, \theta_y)$ can be seen as trial parameters of the GWF and should be “integrated” by hand. To this end, we should know the effective Lagrangian $L_{\text{eff}}(\theta, \phi^s)$, which is given as

$$L_{\text{eff}}(\theta) = \langle [\psi^c_G(\theta)] \{\partial_x \psi^c_G(\theta)\} \rangle + \langle [\psi^c_G(\theta)] \{\psi^c_G(\theta)\} \rangle,$$

where $|\psi^c_G(\theta)\rangle$ is the projected mean field state with Chern numbers $C = (C_1, C_0, C_{-1})$ and gauge twist boundary angles $\theta$. The dynamical term $\langle [\psi^c_G(\theta)] \{\partial_x \psi^c_G(\theta)\} \rangle$ is expected to be small and will be dropped in the following discussion. The consequence of the dynamic term will be discussed in section IV B. The topological term $\langle [\psi^c_G(\theta)] \{\partial_x \psi^c_G(\theta)\} \rangle$ is the Berry phase of Gutzwiller projected states,

$$\exp\{ - \frac{i}{2\pi} \oint_B \theta \cdot \mathbf{A}(\theta) d\theta \} \approx \prod \langle [\psi^c_G(\theta)] \{\psi^c_G(\theta + \delta \theta)\} \rangle.$$

The Berry phase is calculated by the wave function overlap (see Appendix B). Then we can calculate the Berry curvature $\mathcal{F}\mathcal{F}(\theta) = \partial_{\theta_x} A_y - \partial_{\theta_y} A_x$ and the Chern number on the torus formed by the gauge twisted boundary angles,

$$k = \frac{1}{2\pi} \oint_B \theta \cdot \mathbf{A}(\theta) = \frac{1}{2\pi} \int_{\text{torus}} d\theta_x d\theta_y \mathcal{F} \mathcal{F}(\theta),$$

where $B$ is a big loop that encloses the total area of the torus. It turns out that the Berry curvature is uniform on the $(\theta_x, \theta_y)$ torus. If we treat $(\theta_x, \theta_y)$ as the coordinates of a single particle on a torus, then the Berry curvature is the magnetic field that couples to the particle, and $L_{\text{eff}}(\theta)$ can be written as

$$L_{\text{eff}}(\theta) = \frac{i}{2\pi} k \frac{\partial x}{\partial_s} \theta_y,$$

where $2\pi k$ is the strength of the “magnetic field”. From above Lagrangian, it can be shown (see Appendix C1) that the ground state degeneracy of the system is equal to $k$.

The Hall conductance can be measured by coupling the system to a symmetry flux, or symmetry twisted angles $\phi^s = (\phi_x^s, \phi_y^s)$. Now the GWF depends on both $\theta$ and $\phi^s$. The effective Lagrangian is given by $L_{\text{eff}}(\theta, \phi^s) = \langle [\psi^c_G(\theta, \phi^s)] \{\partial_x \psi^c_G(\theta, \phi^s)\} \rangle$. Similar to previous discussion, the effective Lagrangian can also be written as

$$L_{\text{eff}}(\theta, \phi^s) = \frac{i}{2\pi} \sum_m \left( C_m \left( \delta \theta_x + q_m \delta \phi_x^s \right) + C_m \delta \phi_y^s \right).$$

The angles $\theta$ are fluctuating and we should integrate it by hand. Rewriting $\theta = \bar{\theta} + \delta \theta$, where

$$\bar{\theta} = \frac{\sum_m C_m q_m \phi^s}{\sum_m C_m},$$

is obtained from $\frac{\delta L_{\text{eff}}}{\delta \bar{\theta}} = 0$, then

$$L_{\text{eff}}(\theta, \phi^s) = \frac{i}{2\pi} \sum_m \left( \phi_m \phi_x^s + \delta \bar{\theta} x + \delta \bar{\theta} y \right),$$

where $\phi_m$ is defined previously. The first term in the bracket is the physical response and the second term gives the ground state degeneracy.
The Hall conductance can be calculated from Chern number. When adiabatically varying the symmetry fluxes $\phi^s$, we obtain the Berry phase
$$e^{iA(\phi^s)\delta\phi^s} = \langle P_C \psi_C(\phi^s, \tilde{\theta}) | P_C \psi_C(\phi^s + \delta\phi^s, \tilde{\theta} + \delta\theta) \rangle.$$ Integration of the Berry curvature $\mathcal{F}(\phi^s) = \partial_{\phi^s} A_y - \partial_{\phi^s} A_x$ on the $(\phi_x^s, \phi_y^s)$ torus gives the Hall conductance
$$2\pi \sigma_H = \oint_B d\phi^s \cdot A(\phi^s) = \int_{\text{torus}} d\phi_x^s d\phi_y^s \mathcal{F}(\phi^s),$$
where $B$ is a big loop that encloses the total area of the torus.

The internal back ground gauge flux $\tilde{\theta}$ in above discussion [or $\tilde{a}_\mu$ in (6)] is very important. Without $\tilde{\theta}$ (or $\tilde{a}_\mu$), GWF will give incorrect responses. To see why $\tilde{\theta}$ (or $\tilde{a}_\mu$) is important, we consider the electromagnetic response as an example. It is known that a spin system is a Mott insulator having no charge response. However, if we barely couple the electromagnetic field $A^c_\mu$ to the fermions, after Gutzwiller projection the GWF still has dependence on $\phi^c$ (or $A^c_\mu$), and the Chern-number for the GWF on the twisted-boundary-angle torus formed by $\phi^c$ is nonzero. This seems to indicate that the system still have electromagnetic quantum Hall effect. This is obviously wrong. To obtain the correct response, we need to couple both $A^c_\mu$ and $\tilde{a}_\mu$ to the fermions. Since $q^c = (1, 1, 1)^T$, from (10), $\tilde{\theta} = -\phi^c$ (or $\tilde{a}_\mu = -A^c_\mu$), so the mean field state and the projected state are independent on $\phi^c$ (or $A^c_\mu$), which is consistent with the fact that the system is an insulator.

**IV. NUMERICAL RESULTS**

In this section, we present our numerical results. We will focus on the physical properties of the state $P_C|1\sim 11\rangle$, from which we can judge if it is a SPT state or not. As a comparison, the chiral spin liquid (CSL) state $P_C|11\rangle$, which carries intrinsic topological order, is also studied.

**A. Short range correlation in the bulk**

We first check that the bulk is gapped without symmetry breaking. To this end, we calculate the spin-spin correlation $\langle S_x^z S_{x+1}^z \rangle$ and quadrupole-quadrupole correlation $\langle Q_x^z Q_{x+1}^z \rangle$, where $Q_x = S_x^z - S_y^z$. As shown in Fig. 2, the correlations are weak and extremely short-ranged (about 2 lattice-constants). This indicates that the bulk has a finite excitation gap and no symmetry breaking (otherwise the correlation will be long-ranged).

**B. Trivial Topological Order**

Here we check if the state $P_C|1\sim 11\rangle$ has topological order by calculating its topological entanglement entropy (TEE) and ground state degeneracy.

Using Monte Carlo method, we can obtain the TEE from the second Renyi entropy $S^{(2)} = -\text{Tr} \rho_A^2$, where $\rho_A$ is the reduced density matrix of a subsystem $A$. For
topologically ordered states, the entanglement entropy have an universal correction to the area law,

\[ S^{(2)} = \alpha A - \gamma, \]

where \( A \) is the area of the boundary of the subsystem \( A \), and \( \gamma \) is called the topological entanglement entropy. If \( P_G|1-11\) is a SPT state (which is short range entangled), its TEE \( \gamma \) should be zero.

This is checked numerically. We consider a torus and cut it along \( x \) direction to divide it into two pieces, each piece contains two non-contractable boundaries (see Fig. 3(b)). Area law suggest that the second Renyi entanglement entropy is proportional to the circumference of the cut (\( L_z \)). In Fig. 3(c), we fix \( L_y = 10 \) and plot the entropy with \( L_z \). The TEE is given by the intersect, which is very close to 0. The inset shows the dependence of the TEE \( \gamma \) on \( L_y \). The result is that \( \gamma \) exponentially decays to 0 with increasing \( L_y \). The vanishing TEE implies that the state \( P_G|1-11\) is indeed topologically trivial.

The trivial topological order carried by \( P_G|1-11\) can also be reflected by its non-degeneracy on torus. The ground state degeneracy \( k \) can be obtained through (8). Our numerical result shows the Chern number of \( P_G|1-11\) is 1, while the Chern number for the CSL state \( P_G|111\) is 3, in agreement with theoretical prediction \( k = \sum_m C_m \).

To verify that the ground state degeneracy is indeed equal to \( k \), we calculate the density matrix of projected states with different twisted-boundary angles,

\[ \rho(\theta, \theta') = \langle P_G \psi_C(\theta)|P_G \psi_C(\theta') \rangle. \]  

The eigen states of above density matrix are the orthogonal bases of the Hilbert space spanned by the projected states. In numerical calculation, the torus formed by \( \theta_x \in [0, 2\pi) \) and \( \theta_y \in [0, 2\pi) \) is discretized into \( N \times N \) grids. The eigenvalues of \( \rho \) are proportional to the weights of the corresponding eigen-states in the GWF space. We can normalize the total weight to 1. Our data in Fig. 4 show that the total weight is dominant by the first a few states, and this result is independent on the system size and the number of grids on the \((\theta_x, \theta_y)\) torus.

If a dynamic term \( \frac{i}{g}(\partial_x^2 + \partial_y^2)\) where \( g \) is a non-universal coupling constant determining the internal gauge “photon” gap is added to Eq. (9), then it describes a single particle moving on a tours in an uniform magnetic field with strength \( 2\pi k \). The eigen states are Landau levels and the lowest Landau level correspond to the ground state of the spin system. When \( g \to \infty \), the gap is infinitely large and only the ground states remain. Generally \( g \) is finite and excited states occur in the PWF space with a weigh \( \propto e^{-\beta \varepsilon_i} \), where \( \beta \) is a constant and \( \varepsilon_i \) is the energy of the \( i \)th excited state (i.e. the \( i \)th Landau level). This is the reason why there are some small weight eigenvalues appearing in Fig. 4. Furthermore, the degeneracy of eigenvalues of \( \rho \) reflects the degeneracy of the Landau levels, namely, the degeneracy of eigen states of the spin system on a torus. From Fig. 4(b), we can learn that all the eigenvalues of \( \rho \) for \( P_G|111\) are 3-fold degenerate (within tolerable error), so the ground state is three-fold degenerate. However, for the state \( P_G|1-11\), all the eigenvalues of \( \rho \) are non-degenerate, indicating that the ground state is unique.

**C. Even-Quantized Hall conductance**

We adopt Laughlin’s gauge invariant argument on a cylinder to measure the Hall conductances. To this end, we adiabatically insert a \( U(1) \) symmetry flux quanta \( \phi^a \) into the cylinder and detect the \( U(1) \) symmetry charge pumped from the bottom boundary to the top boundary. Since there are two \( U(1) \) symmetries, we measure the Hall conductance respectively. During the measurement, we used the response mean field Hamiltonian (7) to obtain the GWFs. Our numerical results of \( \sigma_H^{S^z} \) and \( \sigma_H^{S^z} \) are

**FIG. 4.** (Color online) The biggest 9 (normalized) eigenvalues of the density matrix \( \rho \) are shown, which almost exhaust the total weight 1. (a) data for \( P_G|1-11\); (b) data for \( P_G|111\). The results are almost independent on the system size \( L_x, L_y \) (the number of sites is equal to \( L_x \times L_y \times 3 \)) and the number of grids \( N \times N \) by which the torus is discretized.

**FIG. 5.** (Color online) Symmetry charge pumping caused by inserting symmetry fluxes. The Hall conductance is equal to the charge pump by a flux quanta. (a) for the first \( U(1) \) symmetry, the Hall conductance is equal to \( \frac{1}{2\pi} \); (b) for the second \( U(1) \) symmetry, the Hall conductance is equal to \( -\frac{1}{2\pi} \).

FIG. 6. (Color online) Power law decaying correlation function on the boundary (the upper boundary of Fig. 1a,b,c) shows that the edge states are gapless. The inset is a log-log fitting. The horizontal axel is set as ln(sin(πx/Lx)) because of finite size effect.

shown in Fig. 5 and the crossed Hall conductance \( \sigma_{H}^{S_{z}S_{z}} \) is zero. All the Hall conductances are even integers, in consistent with Chern-Simons theory predictions.

The spin Hall conductance can also be calculated by measuring the Chern number [see eq. (11)] of the projected states in torus formed by the \( U(1) \) symmetry twisted boundary angles. Our numerical results confirms the spin Hall conductance shown in Fig. 5.

D. Symmetry protected Gapless boundary states

As mentioned, the spin-spin correlation function in the bulk is short ranged and boring. But the boundary is nontrivial. The nonzero Hall conductance indicates that the boundary should be gapless and the correlation function should be power law decaying. We would like to directly confirm the power law behavior for the boundary states. We calculate the correlation function \( \langle Q_{x}^z(r)Q_{x}^z(r+x) \rangle \) (where \( Q_{x}^z = S_{x}^z - S_{y}^z \)) on the boundary (along \( x \) direction) of a cylinder of 300 sites. The cylinder has \( L_x \times L_y = 20 \times 5 \) = 100 unit cells and is periodic in \( x \) direction and open in \( y \) direction (see Fig. 1b). The result shows perfect power (see Fig. 6),

\[
\langle Q_{x}^z(r)Q_{x}^z(r+x) \rangle \sim x^{-2.036}
\]

and the decaying power \(-2.036\) agrees well with conformal field theory prediction \(-2\) (see Appendix C2). It should be noted that the correlation function is very small even on the boundary. This may be owning to the extremely short correlation length on the bulk.

To completely confirm that \( P_G|1-11\rangle \) is a SPT state, we finally need to show that its boundary state is non-chiral, namely, the gapless boundary excitations can be
gapped out by symmetry breaking perturbations. Before projection, the mean field state \( |1-11\rangle \) is obviously chiral and its boundary cannot be gapped out by small local perturbations. To show that the projected state \( P_G|1-11\rangle \) is non-chiral, we calculate the boundary correlation function after adding some symmetry breaking perturbation.

The \( U(1) \) symmetry breaking perturbation that we consider is the following fermion pairing term

\[
H'_{\text{mf}} = \Delta_{j}^{\dagger}c_{1,j}^{\dagger}c_{-1,j} + \Delta_{ij}^{\dagger}c_{i,j}c_{0,j} + h.c.
\]

The spin interaction that support this perturbation might be

\[
H' = -(c_{i,j}^{\dagger}c_{i,j} - c_{-1,j}c_{0,j} + h.c.) = -(P_{i}^{x}Q_{j}^{x} - P_{i}^{y}Q_{j}^{y}),
\]

where \( P^{x} = \frac{1}{\sqrt{2}}(S_{x}S_{z} + S_{z}S_{x} + S_{y}S_{y}) = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, P^{y} = \frac{1}{\sqrt{2}}(S_{y}S_{x} + S_{z}S_{y} + S_{y}S_{x}) = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \) and \( Q^{x} = S_{x}^{2} - S_{y}^{2} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, Q^{y} = S_{x}S_{y} + S_{y}S_{x} = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix}. \) Similar to \( S^{x}, S^{y}, S^{z} \), the three operators \( Q^{x}, Q^{y}, S^{z} \) also form \( SU(2) \) algebra.

Our numerical result is shown in Fig. 7, where the correlation function \( \langle S_{z}^{x}S_{z}^{x} \rangle \) and \( \langle Q_{x}^{x}Q_{x}^{x} \rangle \) are both exponentially decaying as expected.

We also calculate the boundary correlation function of the CSL undergoing the same perturbation. The results in Fig. 8 show that the boundary remains gapless under the perturbation. This comparison give strong evidence
that the boundary of the state $P_G|111\rangle$ is non-chiral while the CSL state $P_G|111\rangle$ is chiral, as predicted by Chern-Simons theory (see Appendix C2).

V. CONCLUSION AND DISCUSSION

In summary, using Monte Carlo method we studied the physical properties of Gutzwiller projected wave functions. We especially studied the state $P_G|111\rangle$ (where 1, −1, 1 are the mean field Chern numbers of the fermions $f_1$, $f_0$, $f_{-1}$, respectively), including its spin Hall conductance, correlation function of the gapless edge states, ground state degeneracy and topological entanglement entropy, and non-robustness of the gapless edge states. All these evidence show that $P_G|111\rangle$ is a $U(1) \times U(1)$ symmetry protected topological state. Our work may shed some light on simple lattice models and experimental realization of SPT phases.

The spin Hall conductance is calculated by measuring the spin pump in the Gutzwiller wave function caused by inserting symmetry flux through the cylinder to the mean field Hamiltonian. We find that the internal gauge field plays an important role since external symmetry flux will induce a non-zero background internal gauge flux (see also Ref. 40). Our observation indicates that in general internal gauge field can not ignored in studying physical response of Gutzwiller projected wave functions.

We also compared the SPT state $P_G|111\rangle$ with the topologically ordered chiral spin liquid state $P_G|111\rangle$ whose gapless boundary excitations are robust against all local perturbations. Our data imply that the boundary of the SPT state is non-chiral while the boundary of the chiral spin liquid is chiral. Noticing that at mean field level both $|1 − 11\rangle$ and $|111\rangle$ are chiral, it is remarkable that after Gutzwiller projection (or owning to strong interactions) the former becomes non-chiral. This indicates that physical properties of some mean field states might be dramatically changed after Gutzwiller projection.

Our Gutzwiller approach can be applied to study SPT states protected by other symmetry groups, such as $SU(2)$ or $SO(3)$ symmetry, and so on. It can be also used to study symmetry enriched topological phases, where symmetry interplays with topological order resulting in an enriched phase diagram.

Appendix A: Topological Entanglement Entropy

In Ref. 48–52, several tricks has been introduced to calculate Renyi entropy. The main trick is ‘sign trick’ which separates the calculation of the magnitude and phase of the swap operator:

$$e^{-S_2} = \langle\text{SWAP}\rangle = \sum_{\alpha_1, \alpha_2} \rho_{\alpha_1, \alpha_2} \frac{\phi_{\beta_1} \phi_{\beta_2}}{\phi_{\alpha_1} \phi_{\alpha_2}} \tag{A1}$$

where $\alpha_1, \alpha_2$ are the spin configurations of two independent systems of the same size, $\beta_1, \beta_2$ are the spin configurations after the swapping the spins in the holes, and

$$\langle\text{SWAP}\rangle_{\text{phs}} = \sum_{\alpha_1, \alpha_2} \tilde{\rho}_{\alpha_1, \alpha_2} e^{i\phi} \tag{A2}$$

with $\phi = \text{Arg}(\phi^*_{\alpha_1} \phi^*_{\alpha_2} \phi_{\beta_1} \phi_{\beta_2})$ and $\tilde{\rho}_{\alpha_1, \alpha_2} = |\phi^*_{\alpha_1} \phi^*_{\alpha_2} \phi_{\beta_1} \phi_{\beta_2}|$.\langle\text{SWAP}\rangle_{\text{amp}} = \sum_{\alpha_1, \alpha_2} |\phi^*_{\alpha_1} \phi^*_{\alpha_2} \phi_{\beta_1} \phi_{\beta_2}| \tag{A3}

$$= \sum_{\alpha_1, \alpha_2} \rho_{\alpha_1, \alpha_2} \left| \frac{\phi_{\beta_1} \phi_{\beta_2}}{\phi_{\alpha_1} \phi_{\alpha_2}} \right|$$

When calculating the phase part, since both the spin configurations before and after the swapping appear in the sampling weight, the trick of updating the inverse and determinant can be applied in the Monte Carlo steps. However, this trick can not be applied to the magnitude part since the swapped configuration may have zero weight and $\phi_{\beta_1}, \phi_{\beta_2}$ may not change continuously. To solve this
problem and to decrease the error, here we further use the trick to separate the calculating the magnitude into two steps, in each step, the matrix inverse and determinant updating techniques can be applied. The main idea is to introduce a weight function \( f(\alpha_1, \alpha_2) \):

\[
 f(\alpha_1, \alpha_2) = \begin{cases} 
 1, & \text{if } \beta_1, \beta_2 \text{ are allowed} \\
 0, & \text{if } \beta_1, \beta_2 \text{ are not allowed}
\end{cases}
\]  

(A4)
such that

\[
\langle \text{SWAP} \rangle_{\text{amp}} = \sum_{\alpha_1, \alpha_2} f(\alpha_1, \alpha_2) \rho_{\alpha_1} \rho_{\alpha_2} \left| \phi_{\beta_1} \phi_{\beta_2} \right|_{\phi_{\alpha_1} \phi_{\alpha_2}}
\]

\[
= \sum_{\alpha_1, \alpha_2} \rho'(\alpha_1, \alpha_2) \frac{\phi_{\beta_1} \phi_{\beta_2}}{\phi_{\alpha_1} \phi_{\alpha_2}} \langle f(\alpha_1, \alpha_2) \rangle
\]

\[
= \langle \text{SWAP} \rangle'_{\text{amp}}(f(\alpha_1, \alpha_2))
\]  

(A5)

where \( \rho'(\alpha_1, \alpha_2) = \frac{f(\alpha_1, \alpha_2) \rho_{\alpha_1} \rho_{\alpha_2}}{\langle f(\alpha_1, \alpha_2) \rangle} \), and

\[
\langle f(\alpha_1, \alpha_2) \rangle = \sum_{\alpha_1, \alpha_2} \rho_{\alpha_1} \rho_{\alpha_2} f(\alpha_1, \alpha_2).
\]

Since \( f(\alpha_1, \alpha_2) \) is a simple function taking values 0 and 1, the fluctuation is reduced considerably compared to \( \langle \text{SWAP} \rangle_{\text{amp}} \) itself.

**Appendix B: Overlap of wave functions**

Suppose two normalized wave functions \(|\psi_1\rangle\) and \(|\psi_2\rangle\) are given as

\[
|\psi_1\rangle = \sum_\alpha \frac{f_1(\alpha)}{\sqrt{\sum_\beta |f_1(\beta)|^2}} |\alpha\rangle,
\]

\[
|\psi_2\rangle = \sum_\alpha \frac{f_2(\alpha)}{\sqrt{\sum_\beta |f_2(\beta)|^2}} |\alpha\rangle,
\]

where \( \alpha \) means a spin configuration. To calculate the overlap between the two states \(|\psi_1\rangle |\psi_2\rangle\), we introduce another normalized wave function \(|\psi_0\rangle\) to generate the Monte Carlo sequence,

\[
|\psi_0\rangle = \sum_\alpha \frac{h(\alpha)}{\sqrt{\sum_\beta |h(\beta)|^2}} |\alpha\rangle = \sum_\alpha W_\alpha |\alpha\rangle,
\]

where \( W_\alpha = \frac{h(\alpha)}{\sqrt{\sum_\beta |h(\beta)|^2}} \) is the weight of \( \alpha \).

Now we have

\[
\langle \psi_1 | \psi_2 \rangle = \sum_\alpha \frac{f_1^*(\alpha) f_2(\alpha)}{\sqrt{\sum_\beta |f_1(\beta)|^2 \sum_\gamma |f_2(\gamma)|^2}}
\]

\[
= \sum_\alpha W_\alpha f_1^*(\alpha) f_2(\alpha) \frac{\sum_\gamma |h(\gamma)|^2}{h^*(\alpha) h(\alpha) \sqrt{\sum_\beta |f_1(\beta)|^2 \sum_\gamma |f_2(\gamma)|^2}}
\]

\[
= \frac{1}{C} \sum_\alpha W_\alpha f_1^*(\alpha) f_2(\alpha) \frac{h^*(\alpha) h(\alpha)}{h^*(\alpha) h(\alpha)},
\]  

(B1)

where \( C \) is a constant:

\[
C = \sqrt{\sum_\beta |f_1(\beta)|^2 \sum_\gamma |f_2(\gamma)|^2}
\]

\[
= \sqrt{\sum_\beta W_\beta |f_1(\beta)|^2 \sum_\gamma W_\gamma |f_2(\gamma)|^2}
\]  

(B2)

**Appendix C: Ground State Degeneracy and Boundary theory**

1. **Ground State Degeneracy**

If we integrate out the \( a_{\mu} \) fields in the Chern-Simons action (2), we obtain

\[
\mathcal{L}_{\text{eff}}(\hat{\alpha}) = \frac{i}{4\pi} k \varepsilon^{\mu\nu\lambda} \hat{\alpha}_\mu \partial_\nu \hat{\alpha}_\lambda,
\]  

(C1)

where \( k = \sum_m C_m \). If we further integrate out the \( \hat{a}_0 \) field, we obtain a zero-strength condition

\[
\partial_x \hat{a}_y - \partial_y \hat{a}_x = 0.
\]

So we can write \( \hat{a}_i = \partial_i \Lambda + \theta_i / L_i \), where \( L_i \) is the size along \( i \) direction and \( \theta_i \) can be interpreted as the angle of twisted boundary condition for the fermionic spinons, or the gauge flux through the \( i \)th hole of the torus. Substituting above expression into (C1), we get the effective action

\[
L_{\text{eff}} = \frac{i}{2\pi} k \theta_x \theta_y,
\]  

(C2)

which yields \( [\theta_x, \frac{k}{2\pi} \theta_y] = i \). Define operators \( T_i = e^{i \theta_i} \), then we have

\[
T_x T_y = T_y T_x e^{i \frac{\pi}{k}}
\]  

(C3)

which form a Heisenberg algebra.

Noticing \( \hat{a}_0 = 0 \) is nothing but the chemical potential \( \lambda_i \) in (1), integrating out \( \hat{a}_0 \) results in exactly one fermion per site, which is equivalent to a Gutzwiller projection. Eqn. (C2) shows that the GWF still have some degrees of freedom, which determines the ground state degeneracy.

The representation space of above Heisenberg algebra (C3) is at least \( k \)-dimensional. Since \( \hat{a}_\mu \) is a gauge degree of freedom for the original spin model, \( T_x \) and \( T_y \) will not change the spin Hamiltonian, namely, \([T_x, H] = [T_y, H] = 0\). So the Hilbert space of each energy level forms a representation space of the Heisenberg algebra. In other words, all the energy levels, including the ground state, are at least \( k \)-fold degenerate.

The degeneracy of the ground states can be obtained by calculating the Chern number for the Gutzwiller projected mean field states. At the mean field level, \( \theta_x \) and \( \theta_y \) are commuting, so we can construct mean field states with certain values of \( \theta_x, \theta_y \), noted as \(|\psi_{C_1 C_0 C_{-1}}(\theta_x, \theta_y)\rangle\), where \( C \) denotes \( (C_1 C_0 C_{-1}) \) for short. The topological term (C2)
plays its role when \( a_0 \) is integrated out (or equivalently after Gutzwiller projection). If we interpret the topological term (C2) as the Berry phase of the Gutzwiller projected state evolving on the \((\theta_x, \theta_y)\) torus,

\[
\frac{i}{2\pi} \oint_{\theta} \frac{k}{2\pi} \hat{\theta}_x \theta_y = \langle P_G \psi_C(\theta_x, \theta_y) | \partial_{\theta} | P_G \psi_C(\theta_x, \theta_y) \rangle,
\]

then \( k \) corresponds to the Chern number of the projected state,

\[
2\pi k = \oint_B \frac{k}{2\pi} \hat{\theta}_x \theta_y d\tau = \oint_{\text{torus}} d\theta_x d\theta_y F(\theta),
\]

where \( A = -i (P_G \psi_C(\theta_x, \theta_y) | \partial_{\theta} | P_G \psi_C(\theta_x, \theta_y) \rangle \) is the Berry connection (if \( \theta_x, \theta_y \) are discretized, then we have \( e^{iA_0} = \langle P_G \psi_C(\theta_x, \theta_y) | P_G \psi_C(\theta_x + \theta_0, \theta_y) \rangle \) and \( F(\theta) = \partial_{\theta_x} A_y - \partial_{\theta_y} A_x \) is the Berry curvature, \( B \) is the big loop enclosing the total area of the \((\theta_x, \theta_y)\) torus.

Generally, the projected state \( |P_G \psi_C(\theta_x, \theta_y)\rangle \) is not an eigenstate of \( T_j = e^{i\theta_j} \). In stead, an eigen state \( |n_i\rangle \) of \( T_i |n_i\rangle = e^{i\theta_i/n} |n_i\rangle \) (here \( n = 0, 1, \ldots, k-1 \)) is a superposition of \( |P_G \psi_C(\theta_x, \theta_y)\rangle \),

\[
|n_i\rangle = \int d\theta_x d\theta_y \xi_n(\theta_x, \theta_y) |P_G \psi_C(\theta_x, \theta_y)\rangle,
\]

where \( \xi_n(\theta_x, \theta_y) \) is a weight function in analog to a single particle wavefunction in the first Landau level.\(^{53}\)

### 2. Boundary theory

In the remaining part, we will introduce an equivalent \( K \)-matrix description as the low energy effective theory. Integrating out the internal gauge field \( \hat{a}_\mu \) first, we obtain \( \sum_m \hat{a}_m a_m \lambda = 0 \), or \( \sum_m \hat{a}_m \lambda = 0 \) up to a constant field. Eliminating \( a_\mu \), we obtain the low energy effective Chern-Simons theory for the spin system,\(^{87}\)

\[
\mathcal{L} = -\frac{i}{4\pi} \varepsilon^{\mu \nu \lambda} (a_{1 \mu} a_{-1 \lambda} + a_{-1 \mu} a_{1 \lambda}) K \partial_\nu \left( \begin{array}{c} a_{1 \lambda} \\ a_{-1 \lambda} \end{array} \right) + \frac{i}{2\pi} \varepsilon^{\mu \nu \lambda} A_\mu^\lambda (q_1 \ q_{-1}) \partial_\nu \left( \begin{array}{c} a_{1 \lambda} \\ a_{-1 \lambda} \end{array} \right),
\]

where \( K = \begin{pmatrix} C^{-1} + C_0^{-1} & C_0^{-1} \\ C_0^{-1} & C^{-1} + C_0^{-1} \end{pmatrix} \), \( A_\mu^\lambda \) is the probing field according to some symmetry and \( q = \begin{pmatrix} q_1 \\ q_{-1} \end{pmatrix} \) is the “charge vector” coupling to this probe field. For the \( \sum_i S_i^z \) conservation symmetry, \( q = \begin{pmatrix} 1 \\ -1 \end{pmatrix} \), while for the \( \sum_i (S_i^z)^2 \) conservation symmetry, \( q = \begin{pmatrix} 1 \\ 1 \end{pmatrix} \). The Hall conductance is given by \( \sigma_H = \frac{1}{\pi} q^T K^{-1} q \).

Since (C8) is not gauge invariant if the system has a boundary, we need to introduce a boundary action to recover the gauge invariance,

\[
\mathcal{L}_{\text{boundary}} = -\frac{i}{4\pi} K_{IJ} \partial_\nu \phi_I \partial_\nu \phi_J - V_{IJ} \partial_\nu \phi_I \partial_\nu \phi_J \quad \text{(C9)}
\]

where \( I, J = 1, -1 \), the field \( \phi_I \) only exist on the boundary and is defined such that \( a_{1 \mu} = \partial_\nu \phi_I \). The \( \phi_I \) field satisfy the Kac-Moody algebra

\[
[\partial_\nu \phi_I, \partial_\nu \phi_J] = 2\pi i K_{IJ} \partial_\nu \delta(x - y). \quad \text{(C10)}
\]

The fermion operators can be written as \( f_1 \sim e^{-i\phi_1}, f_{-1} \sim e^{-i\phi_{-1}} \). The spin density operator is given as \( S_z \sim \partial_\nu \phi_1 - \partial_\nu \phi_{-1} \), and

\[
Q^\pm = \frac{1}{2} (Q^x \pm iQ^y) \sim e^{i\phi_1 \pm i\phi_{-1}}. \quad \text{(C11)}
\]

If \( C_1 = 1, C_0 = -1, C_{-1} = 1 \), then the \( K \) matrix is given as \( K = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} \), from (C10) and (C11), we obtain the scaling law

\[
\langle Q^+(r) Q^-(r + x) \rangle \sim x^{-2},
\]

which is verified by the numerical result given in section III.

Furthermore, for above \( K \) matrix, since \( l = \begin{pmatrix} n \\ 0 \end{pmatrix} \) or \( l = \begin{pmatrix} 0 \\ n \end{pmatrix} \) (\( n \) is an integer) satisfies

\[
l^T K^{-1} l = 0, \quad \text{(C12)}
\]

the Higgs term\(^{24}\) that may gap out the boundary is \( \cos(n\phi_1) \) or \( \cos(n\phi_{-1}) \). Eq. (C12) is the gapping condition for the perturbations. For instance, the pairing perturbation discussed in section IV D satisfy the gapping condition. On the other hand, if this condition is
not satisfied for some perturbation, for example, a Zeeman field coupling

$$H' = B_x S_x \sim \cos(2\phi_1 + \phi_{-1}) + \cos(2\phi_{-1} + \phi_1)$$

which does not contain the Higgs term, then the boundary remains gapless even the symmetry is explicitly broken. This is verified by our numerical result shown in Fig. 9, where the correlation function \(\langle Q^x(r)Q^x(r+x)\rangle\) remains power law if we add a Zeeman field \(B_x = 0.4\) (in units of \(t_{ij}\)) to the whole system.

Finally, we give the Chern-Simons theory of the CSL state where \(C_1 = C_0 = C_{-1} = 1\). Form (C8), the \(K\) matrix of the CSL is given as \(K = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}\). Since \(\det K = 3\), the ground state degeneracy of CSL on a torus is 3. Furthermore, since the gapping condition (C12) has no solutions, the boundary can not be gapped out by small local perturbations.
