Significance of the Study

- Solitary single-cavity renal hydatid cysts with a “double-contour” appearance have been rarely described and may warrant studying. Misdiagnosis of the lesion as a renal tumor indicated radical nephrectomy with retrograde diagnosis. Isolated renal hydatid cyst should be considered during differential diagnosis of renal cystic lesions.

Keywords
Renal hydatid cyst · Cystic renal tumor · \textit{Echinococcus granulosus} · Renal pseudotumor

Abstract

Objective: The aim of this work is the presentation of a case of isolated renal hydatid cyst with novel findings and an unusual surgical scenario. Clinical Presentation and Intervention: A 54-year-old female patient presented with left loin pain and a palpable left renal mass. Imaging described a well-demarcated left renal cystic lesion with a double-layer wall. Radical nephrectomy was performed due to the possibility of malignancy. On retrograde revision, the double-layer wall represented the detached germinative membrane of a hydatid cyst that was confirmed by histopathology. Conclusion: Isolated renal hydatid cyst could be misinterpreted as a renal tumor. It should be considered in the differential diagnosis of renal cystic lesions.

Introduction

Hydatid disease is a worldwide zoonosis due to a parasitic infestation usually caused by \textit{Echinococcus granulosus}. However, urogenital hydatid disease is a rare pathology comprising only 2–3\% of all cases [1, 2]. Urogenital sites rank third after the liver and lungs, which are the main predilection sites in more than 90\% of cases. Although renal hydatid cyst is the most common form of urogenital hydatidosis, its isolated presentation is an extremely rare clinical entity [3], and it may be misinterpreted as a renal tumor [1, 4].

Case Report

A 54-year-old Egyptian female patient from an urban area presented with left loin pain of 14 months’ duration. Physical examination revealed an average body build and normal vital signs. There was a nontender, fairly palpable left-sided renal mass.
Abdominal ultrasound showed a cystic lesion occupying the lower and mid zones of the left kidney with internal septa, a thickened irregular wall, and turbid contents that looked like soft tissues. Noncontrast computed tomography was performed before presentation of the patient to our center and described a complex cystic mass occupying most of the left kidney with a well-defined outline, thickened wall, and a suggestion of a soft tissue compartment. Its dimensions were 10.5 × 7.0 × 5.5 cm with a hypodense appearance. The thickened wall was double layered in most of its circumference (Fig. 1). Magnetic resonance imaging, scheduled as a complementary study, showed similar findings to computed tomography. Moreover, a diffuse-weighted study failed to prove or exclude the suspicion of malignancy. It suggested an intra-cyst hemorrhage (Fig. 2a, b). Whole body bones, the chest, and other abdominal organs were shown to be free of expected metastases by imaging.

A urine analysis, renal function tests, and routine tests were unremarkable with eosinophilia. Owing to the suspicion of malignancy, open radical nephrectomy was performed through a left subcostal incision. Extensive adhesions were encountered with difficulties in dissection of the mass from the vicinities of the pancreas and spleen due to extensive tissue reactions. However, the operation was completed without rupture in 2 h and 25 min. Blood loss was 250 mL, necessitating the transfusion of 1 unit of blood. The postoperative course was uneventful.

The cut-surface of the mass showed a true and well-developed unilocular cyst involving the major parts of renal parenchyma and lined by a whitish membrane detached from the surrounding walls (Fig. 3). In retrograde revision, the lesion was a renal hydatid cyst and its detached germinative membrane with the reactive capsule was responsible for the thickened double-layer wall appearance. Microscopic and histopathological examinations clearly described and confirmed the diagnosis of renal hydatid cyst (Fig. 4a–d) and excluded malignancy. Clear gross and histopathological pictures reduced the necessity of postoperative serological testing for echinococcosis. However, a course of albendazole, 400 mg twice daily, was prescribed for 4 weeks to reduce the possibilities of a relapse.

**Discussion**

Hydatid disease is a worldwide parasitic infestation transmitted from animals like dogs, which are the primary hosts, to other animals, such as sheep and cattle as the intermediate hosts, to humans. Transmission to humans occurs by ingestion of contaminated soils or vegetables [4]. The current case did not have a clear history of contact with animals. Thus, infestation may have occurred via contaminated foods.

Although it has no specific common clinical presentation, renal hydatid cyst has a suggestive characteristic appearance on imaging, surgical cut-surface, and histopathological examination [4]. The combination of a relevant clinical history, imaging tools, and laboratory investiga-
In the current case, this finding was confirmed by the cut-surface of the mass after nephrectomy. A typical ra-

tions provides a reliable preoperative diagnosis in only half of all cases.

On retrograde revision of the imaging studies in the current case, a well-demarcated unilocular renal cyst was observed. The detached germinative membrane was a double-layered membrane with the cyst wall, which we refer to as a "double-contour" appearance. This appearance has been previously described as a "water-lily sign." Cystic echinococcosis lesions have been classified by the World Health Organization into 5 grades. Grade 1 and 2 represent the early stage of disease where the production of scolices is active. Grade 3 is a transitional stage that represents the start of degeneration of the cyst with detachment of the germinal membrane from the cyst wall. It has been differentiated into grade 3a for a solitary cyst with multiple septa and grade 3b for multiple small cysts in solid parenchymal tissues. Grades 4 and 5 refer to old and degenerative stages of the disease with calcification. Based on this classification, imaging findings of the current case refer to a grade 3a hydatid cyst (G3a) [5–7]. In the current case, this finding was confirmed by the cut-surface of the mass after nephrectomy. A typical radio-

logical picture of a renal hydatid cyst has been described previously as a single unilocular lesion with multiple daughter cysts or vesicles [2]; atypically, daughter cysts may be absent [8]. Similarly, the current case demonstrated only a single unilocular cyst which contributed to the preoperative misdiagnosis of the lesion. An isolated renal hydatid cyst is treated by nephron-sparing surgery in about 75% of cases [1, 8]. Nephrectomy is warranted in the case of preoperative undiagnosed masses [2]. The latter scenario occurred in the current case.

Conclusion

In spite of the characteristic picture of cystic echinococcosis on imaging, an isolated renal hydatid cyst is a very rare lesion which may be misdiagnosed as a renal tumor. This should be taken into consideration in the differential diagnosis of single or multiple renal cystic lesions. It should be considered a tumor until proven otherwise, even in endemic countries for echinococcosis. Nephrectomy is warranted for preoperatively misdiagnosed large lesions and high-grade lesions.
