Abstract

The low-redshift Lyα forest of absorption lines provides a probe of large-scale baryonic structures in the intergalactic medium, some of which may be remnants of physical conditions set up during the epoch of galaxy formation. We discuss our recent Hubble Space Telescope (HST) observations and interpretation of low-z Lyα clouds toward nearby Seyferts and QSOs, including their frequency, space density, estimated mass, association with galaxies, and contribution to Ωb. Our HST/GHRS detections of ∼70 Lyα absorbers with \( N_{HI} \geq 10^{12.6} \) cm\(^{-2}\) along 11 sightlines covering pathlength \( \Delta(cz) = 114,000 \) km s\(^{-1}\) show \( f(>N_{HI}) \propto N_{HI}^{-0.63\pm0.04} \) and a line frequency \( dN/dz = 200 \pm 40 \) for \( N_{HI} > 10^{12.6} \) cm\(^{-2}\) (one every 1500 km s\(^{-1}\) of redshift). A group of strong absorbers toward PKS 2155-304 may be associated with gas \((400 - 800)h_{75}\) kpc from 4 large galaxies, with low metallicity \((\leq 0.003 \) solar) and D/H \( \leq 2 \times 10^{-4} \). At low-z, we derive a metagalactic ionizing radiation field from AGN of \( J_0 = 1.3^{+0.8}_{-0.5} \times 10^{-23} \) ergs cm\(^{-2}\) s\(^{-1}\) Hz\(^{-1}\) sr\(^{-1}\) and a Lyα-forest baryon density \( \Omega_b = (0.008 \pm 0.004)h_{75}^{-1} [J_{-23}N_{14}b_{100}]^{1/2} \) for clouds of characteristic size \( b = (100 \) kpc)\( b_{100} \).

1 Introduction

Since the discovery of the high-redshift Lyα forest over 25 years ago, these abundant absorption features in the spectra of QSOs have been used as evolutionary probes of the intergalactic medium (IGM), galactic halos, and now large-scale structure and chemical evolution. The rapid evolution in the distribution of lines per unit redshift, \( dN/dz \propto (1 + z)^\gamma \) \((\gamma \approx 2.5 \) for \( z \geq 1.6 \)), was consistent with a picture of these features as highly ionized “clouds” whose numbers and sizes were controlled by the evolution of the IGM pressure, the metagalactic ionizing radiation field, and galaxy formation. Early observations also suggested that Lyα clouds had characteristic sizes \( \sim 10 \) kpc, were much more abundant than \( (L_\star) \) galaxies and showed little clustering in velocity space. They were interpreted as pristine, zero-metallicity gas left over from the recombination era. One therefore expected low-redshift \((z < 1)\) absorption clouds to show only traces of H I, due to photoionization and evaporation in a lower pressure IGM. All these ideas have now changed with new data and new theoretical modeling.

Absorption in the Lyα forest of H I (and He II) has long been considered an important tool for studying the high-redshift universe (Miralde-Escudé & Ostriker 1990; Shapiro, Giroux, & Babul 1994; Fardal, Giroux, & Shull 1998). A comparison of the H I and He II absorption lines provides constraints on the photoionizing background radiation, on the history of structure formation, and
Figure 1: Pie-diagram distributions of recession velocity and RA of bright (CfA survey) galaxies and four Ly$\alpha$ absorbers toward Mrk 501 and Mrk 421 (Shull, Stocke, & Penton 1996). Two of these systems lie in voids; the nearest bright galaxies lie $> 4h^{-1}_{75}$ Mpc from the absorber.

The frequency of low-$z$ Ly$\alpha$ lines with $W_\lambda \geq 320$ mÅ reported by the HST/FOS Key Project, $dN/dz = (24.3 \pm 6.6)(1 + z)^{0.58\pm0.50}$ (Bahcall et al. 1996), was considerably higher than a simple extrapolation from the high-redshift forest. These higher-$N_{HI}$ absorbers exhibit associations with galaxies ($D \leq 200h^{-1}_{75}$ kpc) about half the time (Lanzetta et al. 1995).

In HST cycles 4–6, our group began GHRS studies of lower-$N_{HI}$ absorbers toward 15 bright targets (Stocke et al. 1995; Shull, Stocke, & Penton 1996). These low-$z$ targets were chosen because of their well-mapped distributions of foreground galaxies (superclusters and voids). Our
studies were designed to measure the distribution of Lyα absorbers in redshift ($z \leq 0.08$) and column density ($12.5 \leq \log N_{\text{HI}} \leq 16$), to probe their association with galaxies, and to measure their clustering and large-scale structure. Toward 15 targets, we detected $\sim 70$ Lyα systems (plus a number of high-velocity clouds and associated Lyα absorbers) over a cumulated pathlength ($c \Delta z$) $\approx 114,000$ km s$^{-1}$. In cycle 7, we will observe 14 more sightlines with the Space Telescope Imaging Spectrograph (STIS) to double our Lyα sample. The locations of Lyα absorbers toward two of our first sightlines are shown in Figure 1.

In our first 4 sightlines, the frequency of absorbers with $N_{\text{HI}} \geq 10^{13}$ cm$^{-2}$ was $\langle dN/dz \rangle \approx (90 \pm 20)$, corresponding to a local space density, $\phi_0 = (0.7 \text{ Mpc}^{-3})R_{100}^{-2}h_{75}$ for absorber radius (100 kpc)$R_{100}$. This space density is $\sim 40$ times that of bright ($L_*$) galaxies, but similar to that of dwarf galaxies with $L \approx 0.01L_*$. From a statistical, nearest-neighbor analysis, we found that the Lyα clouds have some tendency to associate with large structures of galaxies and to “avoid the voids”. However, for the lower column systems, the nearest bright galaxies are often too far to be physically associated in hydrostatic halos or disks (Maloney 1993; Dove & Shull 1994). Of 10 absorption systems first analyzed (Shull et al. 1996), 3 lie in voids, with the nearest bright galaxies several Mpc distant. In several cases, we identified dwarf H I galaxies within 100–300 kpc using the VLA (Van Gorkom et al. 1996). Figure 2 shows one system toward Mrk 335, where a dwarf galaxy with $M_{\text{HI}} \approx (7 \times 10^7 M_\odot)h_{75}^{-2}$ and offset distance $\sim (100 \text{ kpc})h_{75}^{-1}$ is seen at heliocentric velocity $cz = 1955$ km s$^{-1}$, remarkably near to that of the Lyα absorber. Thus, some of the lower-$N_{\text{HI}}$ absorbers appear to be associated with dwarf galaxies, although much better statistics are needed.

In HST cycle 6, we observed 7 more sightlines with the GHRS/G160M. With better data, we were able to detect weaker Lyα absorption lines, down to 20 mA ($N_{\text{HI}} = 10^{12.6}$ cm$^{-2}$) in some cases. Many of the new sightlines exhibit considerably more Lyα absorbers; for these 15 sightlines, $\langle dN/dz \rangle = 200 \pm 40$ for $N_{\text{HI}} \geq 10^{12.6}$ cm$^{-2}$ or one line every 1500 km s$^{-1}$. Although there is wide variation, this frequency is almost 3 times the value (one every 3400 km s$^{-1}$) reported earlier (Shull et al. 1996) for $N_{\text{HI}} \geq 10^{13}$ cm$^{-2}$. For a curve of growth with $b = 25$ km s$^{-1}$, the 70 Lyα absorbers with $12.6 \leq \log N_{\text{HI}} \leq 14.0$ follow a distribution $f(\geq N_{\text{HI}}) \propto N_{\text{HI}}^{-0.63_{-0.04}^{+0.04}}$, remarkably close to the slope in the high-$z$ Lyα forest. These results have been corrected for incompleteness at
Figure 3: HST/GHRS (G160M) spectrum of PKS 2155-304 (Shull et al. 1998) shows multiple Ly$\alpha$ absorption systems between 1281–1290 Å ($cz = 15,700 – 17,500$ km s$^{-1}$). Upper limits on Si III $\lambda1206.50$ absorption at 1274.7 Å and 1275.2 Å correspond to $[\text{Si/H}] \leq 0.003$ solar abundance.

We turn now to the extraordinary sightline toward PKS 2155-304 (Bruhweiler et al. 1993; Shull et al. 1998). This target exhibits numerous Ly$\alpha$ absorbers (Fig. 3), including a group of strong systems between $cz = 15,700$ and 17,500 km s$^{-1}$. The strong absorbers have an estimated combined column density $N_{\text{HI}} = (2 – 5) \times 10^{16}$ cm$^{-2}$, based on Lyman-limit absorption seen by ORFEUS (Appenzeller et al. 1995). Using the VLA (Van Gorkom et al. 1996; Shull et al. 1998), we have identified these absorbers with the very extended halos or intragroup gas associated with four large galaxies at the same redshift (Fig. 4). The offsets from the sightline to these galaxies are enormous. Despite the kinematic associations, it would be challenging to make a dynamical association with such galaxies. One must extrapolate from the $10^{20}$ cm$^{-2}$ columns seen in galactic 21-cm emission to the range $10^{13–16}$ cm$^{-2}$ probed by Ly$\alpha$ absorption. Much of the strong Ly$\alpha$ absorption may arise in gas of wide extent, $\sim 1$ Mpc in diameter, spread throughout the group of galaxies at $z = 0.057$. Assuming that $\langle N_{\text{HI}} \rangle \approx 2 \times 10^{16}$ cm$^{-2}$ and applying corrections for ionization ($H^0/H \approx 3 \times 10^{-4}$ for $J_0 = 10^{-23}$ and 600 kpc cloud depth) and for helium mass ($Y = 0.24$), the gas mass could total $\sim 10^{12} M_\odot$.

These absorbers offer an excellent opportunity to set stringent limits on heavy-element abundances and D/H in low-metallicity gas in the far regions of such galaxies. For example, no Si III $\lambda1206.50$ absorption is detected (rest equivalent width $W_\lambda \leq 22$ mA or $N_{\text{SiII}} \leq 1.0 \times 10^{12}$ cm$^{-2}$ at 4$\sigma$) at wavelengths corresponding to the strong Ly$\alpha$ absorbers near 1281 Å and 1285 Å. Over a range of photoionization models for $(H^0/H)$ and $(\text{Si}^{+2}/\text{Si})$, this limit corresponds to an abundance $(\text{Si/H}) \leq 0.003(\text{Si/H})_\odot$ for an assumed $N_{\text{HI}} = 2 \times 10^{16}$ cm$^{-2}$ and 300–600 kpc cloud depth (Shull et al. 1998). The lack of observed C IV $\lambda1549$ absorption leads to similar limits, $[\text{C/H}] < 0.005$.
The major uncertainty in deriving absorber masses is the ionization correction, which depends on the profile of gas density around the cloud centers. Assume, for simplicity, that \( n_{\text{H}}(r) = n_0(r/r_0)^{-2} \) and adopt photoionization equilibrium with photoionization rate \( \Gamma_{\text{HI}} \) and a case-A hydrogen recombination rate coefficient, \( \alpha_{\text{H}}^{(A)} \), at 20,000 K. The ionizing radiation field is \( J_\nu = \)

Figure 4: VLA field of 21-cm emission toward PKS 2155-304 at velocities \((16,000 - 17,300 \text{ km s}^{-1})\) near the \( \text{Ly}_\alpha \) absorbers. Four large \( \text{H I} \) galaxies are detected at projected offsets of \((400 - 800)h_{75}^{-1} \text{ kpc} \) (Shull et al. 1998). At least two galaxies, to the south and southwest, appear to be kinematically associated with \( \text{Ly}_\alpha \) absorbers at 16,460 and 17,170 km s\(^{-1}\).

solar. A rudimentary analysis of the lack of observed \( \text{D I} \) (\( \text{Ly}_\alpha \)) absorption in the blueward wings of the strong \( \text{H I} \) lines suggests that \( (\text{D/H}) \leq 2 \times 10^{-4} \). These limits can be improved with more sophisticated profile fitting and future data from HST/STIS (cycle 8) and FUSE.

The \( \text{H I} \) toward PKS 2155-304 appears to represent gas with the lowest detected metallicity. Was this gas was once inside the galaxies at \( cz = 17,000 \pm 1000 \text{ km s}^{-1} \), or is it pristine? We can perhaps answer this question by deeper spectral searches for traces of metals. The origin of the lower-column \( \text{Ly}_\alpha \) systems would seem to be more diverse, possibly arising in extended halos or debris disks of dwarf galaxies, large galaxies, and small groups (Morris & van den Bergh 1994).

3 Theoretical Implications

A primary theoretical issue is whether low-\( z \) clouds have any relation to the evolution of the baryons in the high-\( z \) forest. A quick estimate suggests that the low-\( z \) absorbers could contain a substantial (25%) fraction of the total baryons estimated from Big Bang nucleosynthesis, \( \Omega_{\text{BBN}} = (0.0343 \pm 0.0025)h_{75}^{-2} \) (Burles & Tytler 1998). Consider those \( \text{Ly}_\alpha \) systems with \( N_{\text{HI}} \geq 10^{13} \text{ cm}^{-2} \), for which one can derive the space density \( \phi_0 \),

\[
\frac{dN}{dz} = \phi_0 (\pi R_0^2) \frac{c}{H_0} \approx 100.
\]

The major uncertainty in deriving absorber masses is the ionization correction, which depends on the profile of gas density around the cloud centers. Assume, for simplicity, that \( n_H(r) = n_0(r/r_0)^{-2} \) and adopt photoionization equilibrium with photoionization rate \( \Gamma_{\text{HI}} \) and a case-A hydrogen recombination rate coefficient, \( \alpha_{\text{H}}^{(A)} \), at 20,000 K. The ionizing radiation field is \( J_\nu = \)
Figure 5: Spectrum, $J_\nu(z)$, of ionizing background from redshift $z = 5 \to 0$ from new opacity and radiative transfer models (Fardal, Giroux, & Shull 1998; Shull et al. 1999).

$J_\nu(\nu/\nu_0)^{-\alpha_s}$ with $\alpha_s \approx 1.8$ and $J_0 = (10^{-23}$ ergs cm$^{-2}$ s$^{-1}$ Hz$^{-1}$ sr$^{-1}$)$J_{-23}$. The H I column density integrated through the cloud at impact parameter $b$ is,

$$N_{\text{HI}}(b) = \frac{\pi n_0^2 r_0^4 \alpha_H^{(A)} (1 + 2n_{\text{He}}/n_{\text{H}})}{2\Gamma_{\text{HI}} b^2}.$$ (2)

We can solve for $n_0 r_0^2$ and find the total gas mass within $b = (100$ kpc)$b_{100}$ for a fiducial column density $N_{\text{HI}} = (10^{14}$ cm$^{-2})N_{14}$,

$$M_{\text{cl}}(b) = [4\pi n_0 r_0^2 b(1.22m_H)] = (1.6 \times 10^9 M_\odot)N_{14}^{1/2} J_{-23}^{1/2} b_{500}^{5/2},$$ (3)

which yields a cloud closure parameter in baryons,

$$\Omega_b \approx \phi_0(b) M_{\text{cl}}(b) = (0.008 \pm 0.004) J_{-23}^{1/2} N_{14}^{1/2} b_{100}^{1/2} b_{75}^{-1}.$$ (4)

For the spherical-cloud model, the radiation field, cloud size, and column-density distribution probably each contribute 30–40% to the uncertainty in $\Omega_b$, while temperature $T_e$ and ionizing spectral index $\alpha_s$ contribute 10%, for an overall uncertainty of 50%. However, as with the high-z forest, the greatest uncertainty in $\Omega_b$ lies in the cloud geometry and radial profile. These parameters can only be understood by building up statistics through many sightlines, particularly multiple targets that probe the same cloud structures.

We have also increased our understanding of the metagalactic ionizing background radiation and the “Gunn-Peterson” opacities, $\tau_{\text{HI}}(z)$ and $\tau_{\text{HeII}}(z)$. Using a new cosmological radiative transfer code and IGM opacity model, Fardal, Giroux, & Shull (1998) model the ionization fractions of H I and He II in a fluctuating radiation field due to quasars and starburst galaxies. In this work, we have calculated the metagalactic ionizing radiation field, $J_\nu(z)$, using QSO and stellar emissivities and including cloud diffuse emission and new (somewhat lower) IGM opacities derived from Keck Ly$\alpha$ forest spectra.

Figure 5 illustrates the evolution of $J_\nu$ from $z = 5 \to 0$, peaking at $z \approx 3$. At $z < 2$, the absorption breaks at 1 Ryd (H I) and 4 Ryd (He II) become much less prominent and $J_\nu$ drops rapidly. At low redshift ($z < 0.5$), $J_\nu$ depends both on the local (Seyfert) luminosity function and on the opacity model. We have recomputed the ionizing radiation field at $z \approx 0$ (Shull et al.
1999) using a new opacity model from HST absorption data and extrapolated EUV emissivities of QSOs and low-redshift Seyferts from our IUE-AGN database (Penton & Shull, unpublished). We find $J_0 = (1.3^{+0.8}_{-0.5}) \times 10^{-23}$ ergs cm$^{-2}$ s$^{-1}$ Hz$^{-1}$ sr$^{-1}$ at $z = 0$, very close to our adopted scaling parameter, $J_{-23} = 1$. We clearly still have an enormous amount to learn about the nature and distribution of the low-redshift Ly$\alpha$ clouds. It seems likely that future studies may uncover valuable information about their connection to large-scale structure and to the processes of galaxy formation and evolution.

**Acknowledgements**

Our Ly$\alpha$ observations were made with the NASA/ESA *Hubble Space Telescope* supported by grant GO-06586.01-95A through the Space Telescope Science Institute. Theoretical work was supported by NSF grant AST96-17073. Our colleagues in the VLA studies are Jacqueline Van Gorkom (Columbia University), and Chris Carilli (NRAO). Theoretical work was done in collaboration with Mark Giroux and Mark Fardal (Colorado) and undergraduate research student David Roberts.
