Prevalence of chronic kidney disease in the community using data from OxRen:

a UK population-based cohort study

Abstract

Background
Chronic kidney disease (CKD) is a largely asymptomatic condition of diminished renal function, which may not be detected until advanced stages without screening.

Aim
To establish undiagnosed and overall CKD prevalence using a cross-sectional analysis.

Design and setting
Longitudinal cohort study in UK primary care.

Method
Participants aged ≥60 years were invited to attend CKD screening visits to determine whether they had reduced renal function (estimated glomerular filtration rate [eGFR] ≤60 ml/min/1.73 m² or albumin:creatinine ratio ≥3 mg/mmol). Those with existing CKD, low eGFR, evidence of albuminuria, or two positive screening tests attended a baseline assessment (CKD cohort).

Results
A total of 3207 participants were recruited and 861 attended the baseline assessment. The CKD cohort consisted of 327 people with existing CKD, 257 people with CKD diagnosed through screening (CKD prevalence of 18.2%, 95% confidence interval [CI] = 16.9 to 19.6), and 277 with borderline/transient decreased renal function. In the CKD cohort, 54.4% were female, mean standard deviation (SD) age was 74.0 (SD 6.9) years, and mean eGFR was 58.0 (SD 18.4) ml/min/1.73 m². Of the 586 with confirmed CKD, 44.0% were diagnosed through screening. Over half of the CKD cohort (51.9%, 447/861) fell into CKD stages 3-5 at their baseline assessment, giving an overall prevalence of CKD stages 3-5 of 13.9% (95% CI = 12.8 to 15.1). More people had reduced eGFR using the Modification of Diet in Renal Disease (MDRD) equation than with the CKD Epidemiology Collaboration (CKD-EPI) equation in the 65–75-year age group and more had reduced eGFR using CKD-EPI in the ≥80-year age group.

Conclusion
This study found that around 44.0% of people living with CKD are undiagnosed without screening, and prevalence of CKD stages 1–5 was 18.2% in participants aged ≥60 years. Follow-up will provide data on annual incidence, rate of CKD progression, determinants of rapid progression, and predictors of cardiovascular events.

Keywords
chronic kidney diseases, glomerular filtration rate; kidney failure; OxRen; prevalence; primary health care.

INTRODUCTION
Chronic kidney disease (CKD) is a largely asymptomatic condition of diminished renal function. It has an estimated prevalence in England of 15% in people aged ≥35 years, and an estimated annual cost to the NHS of 1.4 billion GBP. CKD prevalence increases with age and it is independently associated with increased cardiovascular disease risk and all-cause mortality. Having CKD stage ≥3 is the leading risk factor for progression to end-stage renal disease (ESRD) and a strong predictor of hospitalisation. Globally, CKD mortality has increased by one-third over the last 10 years, accounting for 1.2 million deaths annually worldwide.

International guidelines, such as those from the National Institute for Health and Care Excellence (NICE) and Kidney Disease: Improving Global Outcomes (KDIGO), recommend that people with CKD are identified early to address cardiovascular risk, slow CKD progression, and reduce the numbers reaching ESRD and associated costs. Many patients in primary care have CKD that is not formally recognised, and it is unclear whether this has any bearing on their prognosis.

CKD is characterised by measures of renal function including increasing urinary albumin:creatinine ratio (ACR) or decreasing glomerular filtration rate (GFRI), estimated from serum creatinine (eGFR), in line with recommendations from NICE and KDIGO. CKD is classified into stages based on eGFR and ACR cut-offs. Figure 1, adapted from KDIGO guidelines, shows the categories and increased risk of adverse outcomes as CKD stage increases. Many reports of CKD prevalence have only used a single measurement, which may have resulted in biased estimates.

Though CKD is usually asymptomatic until later stages of the disease (stage 4), earlier stages (1–3) are associated with increased mortality and cardiovascular risk. It may therefore be beneficial to establish efficient detection mechanisms for patients with early-stage CKD. Screening enables early detection, but mass screening of all age groups for kidney disease is expensive, of low yield, and not cost-effective. There is an age-related decline in renal function and UK data suggest that this may have been caused by a reduction in the number of people with CKD.
How this fits in

Chronic kidney disease (CKD) is a largely asymptomatic condition with a reported prevalence of around 15% in England in people aged ≥35 years. Routine screening in older people may detect undiagnosed CKD. Using two measurements of serum creatinine and urinary albumin, this study found the prevalence was 18.2% for any-stage CKD and 13.9% in stages 3–5 in an older primary care population (aged ≥60 years). Screening using these two measurements identified that around 8% of older people were living with undiagnosed CKD.

METHOD

Participants aged ≥60 years were recruited in 13 primary care clinics across Oxfordshire, UK, over 44 months, from November 2013 to July 2017. Patients were excluded if they were unable to give informed consent, were terminally ill, had a previous solid organ transplant, or if the GP judged them to be unable to give consent. Eligible participants were invited to attend an initial visit where the study was explained and written informed consent was obtained.

Participants entered the OxRen CKD cohort either on the basis of an existing diagnosis of CKD in their GP records, or through screening. Screening visits involved a serum creatinine test to calculate eGFR and a urinary ACR test. Participants with no previous diagnosis of CKD attended a screening visit (A). If the screening result showed decreased renal function (eGFR <65 ml/min/1.73 m²) or evidence of kidney damage (ACR ≥3 mg/mmol), the participant proceeded to a second screening visit (B) after a 3-month interval to have their CKD diagnosis confirmed. If after this visit, the participant had two abnormal results (eGFR <60 ml/min/1.73 m² or ACR ≥3 mg/mmol), they were classified as having CKD and invited to attend the baseline assessment visit at their GP practice. If on the second occasion the eGFR and ACR did not fall within the criteria for CKD diagnosis, participants were still invited to the baseline assessment visit but classified as having borderline/transient decreased renal function providing their first result suggested CKD stage 1–5. Participants who had a borderline result in their first test and abnormal second test result were also classified as having borderline/transient decreased renal function and invited to attend a baseline assessment. All participants invited to the baseline assessment are hereafter called the CKD cohort (Figure 2).
At the baseline assessment visit, data were collected on demographics, lifestyle, and medical history. Anthropometric and clinical measurements (blood pressure and pulse wave velocity) were made. Questionnaires were completed on diet, physical activity, cognitive function, and quality of life. Blood and urine samples were sent for immediate laboratory analysis, and additional blood and urine samples were collected and stored at −80°C for future genetic and protein testing. All samples were processed across two laboratories using identical instrumentation and assay standardisation. Serum creatinine was measured using an isotope dilution mass spectrometry traceable method and eGFR was reported using the Modification of Diet in Renal Disease (MDRD) equation. The most recent test result was used for 12 participants where no results were available at the time of the test. The effect of these approximations on results was tested by re-analysing data excluding these participants from the analysis.

Data management and reporting
Participants whose laboratory eGFR was reported as >90 ml/min/1.73 m² (n = 2) were...
Designated to have eGFR of 91 ml/min/1.73 m². Urinary albumin levels were approximated to <5 mg/L. These were excluded in a sensitivity analysis in two cases where this may have changed stage of CKD. CKD stage was reported for all participants. Results were tabulated for the full CKD cohort and stratified both by stage of CKD and how the participant entered the cohort (previous diagnosis, new diagnosis, or borderline/transient decreased renal function) to report prevalence and diagnosis, or borderline/transient decreased renal function (49%, N = 277) were classified as having normal kidney function (by KDIGO definition) at their baseline visit. Stage of CKD (20%, N = 327), 58 with newly diagnosed CKD (23%, N = 257), and 135 with borderline/transient decreased renal function (49%, N = 277) were classified as having normal kidney function (by KDIGO definition) at their baseline visit. Stage of CKD and eGFR calculated using the CKD-EPI equation is shown in Supplementary Table S4 and S5, and Supplementary Figure S1. Overall, there were more people with CKD stages 2 and 4 and fewer people with CKD stages 1, 3a, and 3b compared with CKD stage calculated using the MDRD equation. More people had reduced eGFR with CKD stages 1, 3a, and 3b compared with CKD stages 2 and 4 and fewer people.

DISCUSSION

Summary

This large-scale screening study from UK primary care offers a prevalence estimate of 18.2% (95% CI = 16.9 to 19.6) for CKD stages 1–5 in people aged ≥60 years and has found CKD, 44.0% were diagnosed through screening (Figure 2).

Characteristics of the 861 participants who attended a baseline study visit are shown in Table 1. Results are presented for all participants and stratified by whether they had existing CKD, newly diagnosed, or borderline/transient decreased renal function. Briefly, 54.4% were female, mean (SD) age was 74.0 (SD 6.9) years, mean BMI was 28.1 (SD 7.3) kg/m², and 846 (98.3%) were white. Prevalence of hypertension was 59.3% and diabetes was 15.4%. These, and prevalence of other comorbidities, are presented for the full cohort and for different subgroups in Tables 1 and 2, and Supplementary Table S1.

Stratification by stage of CKD using eGFR and ACR shows that 258 participants (30.0%) met the KDIGO definition of normal kidney function (eGFR ≥60 ml/min/1.73 m² and ACR <3 mg/mmol), 34 participants (4.0%) had CKD stage 1, 122 (14.2%) had CKD stage 2, 246 (28.6%) had CKD stage 3a, 133 (15.5%) had CKD stage 3b, 67 (7.8%) had CKD stage 4, and one (0.12%) had stage 5 CKD. Over half of the CKD cohort fell into CKD stages 3–5, which gave a prevalence of CKD stages 3–5 of 13.9% (447/3207) from the full population screened (see Table 2 and Supplementary Table S1). Results were similar in sensitivity analyses where approximations were made (see Supplementary Table S2 for details).

CKD stage of participants stratified by entry to the CKD cohort is shown in Figure 3 and Supplementary Table S3. Sixty-five participants with previously diagnosed CKD (20%, N = 327), 58 with newly diagnosed CKD (23%, N = 257), and 135 with borderline/transient decreased renal function (49%, N = 277) were classified as having normal kidney function (by KDIGO definition) at their baseline visit. Stage of CKD and eGFR calculated using the CKD-EPI equation is shown in Supplementary Table S4 and S5, and Supplementary Figure S1. Overall, there were more people with CKD stages 2 and 4 and fewer people with CKD stages 1, 3a, and 3b compared with CKD stage calculated using the MDRD equation. More people had reduced eGFR (<60 ml/min/1.73 m²) using MDRD than with CKD-EPI in the 60–75-year age group, and more had reduced eGFR using CKD-EPI in the ≥80-year age group (Figure 4).
Table 1. Patient demographics stratified by screening data

| Characteristics                          | Full cohort (N = 861) | Existing CKD (N = 327) | Newly diagnosed CKD (N = 257) | Borderline/transient decreased renal function (N = 277) |
|------------------------------------------|-----------------------|------------------------|-------------------------------|--------------------------------------------------------|
| CKD prevalence, % (95% CI)              | 18.2 (16.9 to 19.6)   | 10.2 (9.2 to 11.3)     | 8.0 (7.1 to 9.0)              | —                                                      |

that 8.0% of this population had CKD that was previously undiagnosed. More than half (51.3%) of those with only a single positive CKD screening test (borderline/transient decreased renal function group), thus not meeting the diagnostic criteria for CKD, were classified into CKD stages 1–4 at the baseline assessment. Providing the baseline samples were taken a minimum of 12 weeks from their previous positive test, these participants now technically meet the diagnostic criteria for CKD.

Strengths and limitations
This study is methodologically strong, using both MDRD and CKD-EPI equations to calculate eGFR and including urinary ACR to estimate CKD prevalence unlike many previous registry studies, which have had less urinary ACR data available. This study reports CKD prevalence by stage of CKD and found that more participants were classified into CKD stage 3a than any other CKD stage. Furthermore, over one-fifth (21.1%) of those with existing CKD were classed as having normal renal function from analysis of blood and urine samples taken at their baseline visit. This highlights how the variability in both eGFR and ACR can result in some participants, who had previously met the diagnostic criteria for CKD, falling into the normal kidney function range on repeat testing. This suggests that there is potential for disease misclassification, which could be an artefact of the interval between screening visits. As more laboratories move away from MDRD to use other equations for estimating GFR, the CKD stage for some individuals may change, and others may no longer meet criteria for diagnosis. Findings from this study corroborate those from other studies, in that moving to CKD-EPI will result in a greater proportion of people aged >75 years having decreased eGFR compared with MDRD and fewer people aged <75 years with reduced eGFR. This analysis has also quantified how moving to the CKD-EPI equation may lead to classification into a different CKD stage for some participants.

There are some limitations to this study. It is possible that people who were aware that they had CKD were more likely to agree to participate in the study, which may have led to an overestimation in the prevalence of CKD in this cohort. Over 98% of the OxRen cohort were white, which is a higher proportion than the 95% white ethnicity reported in the general UK population aged ≥60 years.

Comparison with existing literature
UK prevalence of CKD stages 1–5 in people aged 65–74 years has been reported to be 19%, which is similar to prevalence found in the OxRen cohort. For those >75 years of age, prevalence reaches 46%. A systematic review and meta-analysis reporting global prevalence of CKD stratified by age found a prevalence of CKD stages 1–5 of nearly 28% in populations with a mean age of >60 years and around 34% in those with a mean age of 70 years. These are higher than the prevalence of 18% in the present study, which may reflect differences in the diagnostic criteria used, or prevalence in different ethnic groups and socio-economic status. Other English data suggest that prevalence of CKD stages 3–5 is 12.0–14.5% in those aged 65–74 years. This is similar to the 13.9% (95% CI = 12.8 to 15.1) found in the OxRen cohort despite these surveys using a single eGFR test to classify CKD, which has been shown to overestimate CKD. Internationally, most prevalence estimates in similar age groups are only based on a single test result. In Europe, prevalence differs between countries and ranges from 24% in Norway to 41% in Germany. In the US, prevalence of stages 3–4 is 23%, and stages 1–5 of 34%. A recently published analysis of participants in the OxRen cohort found that using a single screening test to diagnose CKD would result in around 25% over diagnosis because of variability in ACR and eGFR. The results from laboratory analyses at participants’ baseline visit show that some participants’ CKD stage can revert to normal kidney function despite a recent diagnosis. This was observed in 21% of OxRen participants who had received a CKD diagnosis but tested as normal kidney function, based on samples taken during their baseline visit. A combination of analytical and biological variability may have contributed to this. These numbers are consistent with a previous report that found CKD remission rates of 20–30% in follow-up visits in primary care populations with CKD.

Implications for research and practice
This study has found that 8.0% of participants aged ≥60 years had undiagnosed CKD, equating to 44.0% of people living with CKD in this population, and would have remained undiagnosed without screening. This suggests that the early stages of CKD (stages 1–3b) may be under-reported in the literature as many people are unaware that they have the condition. In the UK, some of these people will be picked up in...
Ethical approval
The study protocol was approved by South Central Oxfordshire Research Ethics Committee B [reference number: 13/ SC/0020] and registered with the UK Clinical Research Network [registration number: 36916].

Provenance
Freely submitted; externally peer reviewed.

Competing interests
Nathan Hill became an employee of Bristol-Myers Squibb during the present study. Clare Taylor reports personal fees from Novartis, personal fees from Vifor, and non-financial support from Roche, outside of the submitted work. The remaining authors have declared no competing interests.

the NHS Health Check Programme (www.healthcheck.nhs.uk), which is a 5-yearly free check-up available for adults in the UK aged 40–74 years. However, only 43% of those invited for an NHS Health Check are reported to attend, and it is likely that many non-attenders will be those most at risk.

OxRen provides an estimate of undiagnosed CKD in the UK population aged ≥60 years, including screen-detected rates, and will provide future estimates of incidence. Follow-up will provide evidence on the progression of CKD, and, if progression occurs, identify groups that are most likely to progress, which will make it possible to explore associations with comorbidities and treatments.
