We study the proximity effect of a superconductor to a normal system with fractal spectrum. We find that there is no gap in the excitation spectrum, even in the case where the underlying classical dynamics of the normal system is chaotic. An analytical expression for the distribution of the smallest excitation eigenvalue $E_1$ of the hybrid structure is obtained. On small scales it decays algebraically as $P(E_1) \sim E_1^{-D_1}$, where $D_1$ is the fractal dimension of the spectrum of the normal system. Our theoretical predictions are verified by numerical calculations performed for various models.

PACS numbers: 74.45.+c, 05.45.Mt, 73.23.-b

During the last years there was considerable interest for the study of the statistical properties of hybrid normal-superconductor structures. One of the main outcomes of these studies was the prediction that a normal system in the proximity of a superconductor acquires characteristics that are typical of the superconducting state. Specifically, if the underlying classical dynamics of the normal system is chaotic, an energy gap in the quasiparticle density of states emerges above the Fermi level. Thus, it was natural to substitute the ballistic conductance $MT$ with the appropriate expression $DL^{2-d}$ for diffusive systems. Here $D$ is the classical diffusion coefficient.

Despite all this activity, a significant class of systems was left unexplored. Namely hybrid structures whose normal part has fractal spectra. The latter exhibit energy level statistics that are in strong contrast to the level repulsion predicted by Random Matrix Theory (RMT). Their level spacing distribution follows inverse power laws $P(s) \sim s^{-\beta}$ which is a signature of level clustering. The power $\beta$ was found to be related with the fractal dimension of the spectrum $D_0$ as $\beta = 1 + D_0$. Realizations of this class are quasi-periodic systems with metal-insulator transition at some critical value of the on-site potential like the Harper model, Fibonacci chains, or quantum systems with chaotic classical limit as the Kicked Harper Model. Apart of their own interest the analysis of these systems can be illuminating for the understanding of the behavior of high dimensional disordered systems at the metal-insulator transition like the 3d Anderson model.

Here, for the first time, we present consequences of the fractal nature of the spectrum of the normal system in the excitation spectrum of the hybrid structure. We consider the normal system connected to the superconductor via point contacts supporting $M$ channels and show that there is no gap in the excitation spectrum even in the case where the corresponding classical phase space is chaotic (like in the case of the Kicked Harper model). We derive an analytical expression for the distribution of the minimum excitation eigenvalue $P(E_1)$, and show that its behavior is dictated by the fractal dimension $D_0$ of the
spectrum of the normal part. Thus the nature of the classical dynamics becomes totally irrelevant for these type of systems. Specifically we show that \( \mathcal{P}(E_1) \) generated over different Fermi energies behaves as

\[
\mathcal{P}(\tilde{E}_1) = \left( \frac{1}{D_0} - 1 \right) (\tilde{E}_1 - s_{\text{max}} - 1)
\]  

(2)

where \( \tilde{E}_1 = 2 \frac{E_1}{s_{\text{max}}} \) and \( s_{\text{max}} \) is the maximum level spacing of the normal system within the energy interval that is used in order to generate statistics. Eq. (2) is the main outcome of our investigation. A consequent result is that the mean \( \langle \tilde{E}_1 \rangle \) is given by

\[
\langle \tilde{E}_1 \rangle = \frac{1 - D_0}{2 - D_0}
\]  

(3)

One has to note the lack of any dependence on the system size \( L \) and the number of channels \( M \) in contrast to Eq. (1). Our theoretical results (2,3) are confirmed by numerical calculations performed for various systems with fractal spectra.

Let us start our analysis with the Kicked Harper (KH) model. The system is defined by the time depended Hamiltonian

\[
H = Q \cos(p) + K \cos(\theta) \sum_m \delta(t - mT)
\]  

(4)

where \( p \) denotes the angular momentum, \( \theta \) the conjugate angle, while the kick period is \( T \). Contrary to the standard Harper model (corresponding to the limit \( K \to 0 \)) this model for large enough \( K \geq 5 \) is classically chaotic.

The quantum mechanics of this system is described by a time evolution operator for one period

\[
U = \exp(-i \frac{Q}{\hbar} \cos(h \hat{p})) \exp(-i \frac{K}{\hbar} \cos(x))
\]  

(5)

where \( \hat{p} = -id/d\theta \) is the momentum operator and \( \hbar \) is an effective Planck constant, which includes the frequency ratio of the unperturbed system and the external driving.

For \( K = Q \) the quasi-energy spectrum is fractal [10, 11] and we always consider cases where \( \hbar/2\pi \) is strongly irrational. Using a recently proposed recipe [3] we can write down the corresponding quantum Andreev map \( \mathcal{F} \) and find the quasi-energies of the excitation spectrum of the hybrid structure by direct diagonalization of \( \mathcal{F} \). In all cases considered below we have generated more than 3000 values of \( E_1 \) for statistical processing.

Figure 1 shows \( \mathcal{P}(E_1) \) for various system sizes \( L \) and number of channels \( M \). For small values of \( E_1 \) the distribution of the minimum excitation eigenvalue displays clearly an inverse power law. Moreover, it is independent of the number of channels and system size in agreement with Eq. (2). In the insets of Fig. 1 we also report our results for the mean value of \( E_1 \) for various system sizes and various numbers of channels. The inverse power law character of the distribution \( \mathcal{P}(E_1) \) forces us to conclude that the probability to find a quasi-energy excitation smaller than \( \langle E_1 \rangle \) is high and thus there is no gap in the excitation spectrum (even in a probabilistic sense).

The validity of Eqs. (2,3) can be verified in more cases in the Fibonacci chain model of a one dimensional quasicrystal where various scaling exponents \( D_0 \) can be obtained. The normal system is described by the tight-binding Hamiltonian:

\[
H = \sum_n |n \rangle V_n \langle n | + \sum_n (|n \rangle \langle n + 1 | + |n + 1 \rangle \langle n |)
\]  

(6)

where \( V_n \) is the potential at site \( n \). It only takes the two values \(+V\) and \(-V\) arranged in a Fibonacci sequence [2]. It was shown that the spectrum is a Cantor set with zero Lebesgue- measure for all \( V > 0 \). The sample is in contact with \( M \) semi-infinite one-dimensional superconductors which are attached in \( M \) randomly chosen sites. The quasi-energy spectrum of the hybrid structure is calculated by employing the effective Hamiltonian approach [1]. We again find inverse power laws for the distributions \( \mathcal{P}(E_1) \). Here the exponent depends on the potential strength \( V \), while Eq. (2) still relates the resulting
which are so small that one can consider that they are fractal structure. As a result, most of the eigenstates extended like typical chaotic eigenstates, but they have structure and of the corresponding normal system is evidenced in Fig. 4 where we plot the distribution of the maximum excitation level $\tilde{E}_1$.

Our starting point is the observation that the distribution $P(E_1)$ for $V = 1.4$ and various system sizes $L$ and number of channels $M$. In the insets we also plot the mean value $\langle E_1 \rangle$ of the distribution as a function of system size $L$ and number of channels $M$.

A nice agreement between our numerical data and the theoretical predictions (2,3) is observed [14]. The above results call for a theoretical explanation. In Fig. 2 we report our results for $P(E_1)$ for various $V$'s. The dashed lines are the theoretical predictions [2]; (b) The mean value $\langle E_1 \rangle$ versus the theoretical prediction [3] for various $V$ values. The straight line $y = -0.039 + 0.993x$ represents the best linear fit.

The above results call for a theoretical explanation. Our starting point is the observation that the distribution $P(E_1)$ rescaled in appropriate way is the same for the normal and the hybrid structure. This assumption is verified in Fig. 4 where we plot the distribution of the minimum excitation level $\tilde{E}_1$ for a representative case where the normal part is a Fibonacci lattice with $V = 1.4$. The overlap between the resulting distributions of the hybrid structure and of the corresponding normal system is evident. In order to understand this phenomenon one should recall that the eigenstates of the normal system are not extended like typical chaotic eigenstates, but they have fractal structure. As a result, most of the eigenstates have intensities at the boundary with a superconductor which are so small that one can consider that they are practically not affected by the proximity of the system to the superconductor. Thus these eigenstates and the corresponding eigenenergies are solutions of the eigenvalue problem for the hybrid structure as well. We point here that the perturbative assumption used in our argument, was verified numerically in [15], where it was observed that the effect of the coupling of systems with fractal spectra to external leads is a small perturbation for the most of the eigenstates.

The distribution $P(E_1)$ for the normal system can be derived in the following way. We scan the spectrum of the normal system with a set of Fermi energies which have resolution given by $\epsilon$. Then for fixed $E_1$ we count the number of Fermi energies that are in a distance $E_1$ with tolerance $\epsilon$ from the next larger eigenenergy of the normal system. This is given by the number of level spacings which are larger than $E_1$ i.e. $\int_{s_{\text{max}}}^{s_{\text{max}}} p(s) ds$ where $s_{\text{max}}$ is the maximum level spacing and $p(s)$ is the level spacing distribution. The normalized gap density in the limit of $\epsilon \rightarrow 0$ is then given by

$$P(E_1) = \frac{\int_{s_{\text{max}}}^{s_{\text{max}}} p(s) ds}{\int_{0}^{s_{\text{max}}} dE_1 \int_{E_1}^{s_{\text{max}}} p(s) ds}$$

Substituting in the above equation the expression for $p(s) = s^{-(1+D_0)}$ we eventually get

$$P(\tilde{E}_1) = \frac{1}{D_0 - 1}(\tilde{E}_1^{-D_0} - 1)$$

where $\tilde{E}_1 = \frac{E_1}{s_{\text{max}}}$ is the rescaled energy gap. Notice that an additional factor 2 should be introduced in the definition of the rescaled energy gap i.e. $\tilde{E}_1 = 2\frac{E_1}{s_{\text{max}}}$ once we turn to the distribution of the hybrid structure, due to

FIG. 2: The distribution $P(E_1)$ of a hybrid structure consisting of a a Fibonacci sample of size $L$ (normal part) attached with $M$ semi-infinite one-dimensional superconductors. The data for various $L, M$ fall one on top of the other, indicating that $P(E_1)$ is independent of $L, M$. In the insets we report the mean value $\langle E_1 \rangle$ of the distribution as a function of system size $L$ and number of channels $M$. 

FIG. 3: (a) The distribution $P(E_1)$ for hybrid structures where the normal sample is a Fibonacci lattice with $L = 987$ and $M = 1$ and various $V$'s. The dashed lines are the theoretical predictions [2]; (b) The mean value $\langle E_1 \rangle$ versus the theoretical prediction [3] for various $V$ values. The straight line $y = -0.039 + 0.993x$ represents the best linear fit.
the fact that the excitation levels for the hybrid structure are coming in pairs. In Figs. 1 and 3a we plot with dashed lines the above theoretical prediction. Using Eq. 8 the mean $E_1$ and can be easily evaluated leading to Eq. 9.

In conclusion we have studied the statistical properties of the excitation spectrum of a normal system with fractal spectra at the critical point. We have found that the underlying classical dynamics is irrelevant and that the statistical properties of the quasi-spectrum depends only on the fractal nature of the normal system. Such a system can be realized by a two-dimensional electron gas subject to a perpendicular magnetic field and periodic potential in contact with a superconductor. It is known that the normal system of this type can be mapped onto the Harper model possessing fractal spectrum at the critical point.

Finally, our results can be of interest for the quantum optics community with respect to studies of reflection of light by a dielectric medium in front of a phase-conjugation mirror. This problem is the optics analogue of Andreev reflection. A wave incident at frequency $\omega_0 + \Delta \omega$ is retro-reflected at frequency $\omega_0 - \Delta \omega$ where $\omega_0$ is the pumped frequency of the phase-conjugation mirror. The analogue of $\omega_0$ and of the frequency shifts $\Delta \omega$ are the Fermi energy $E_F$ and the excitation energies $E$ respectively. The latter were shown here to be controlled by the fractal dimension $D_0$. Keeping in mind the above analogies it is reasonable to conjecture that $\Delta \omega$ is controlled as well by $D_0$ in quasi-periodic optical structures like e.g. in Fibonacci quasicrystals. Thus controlling $D_0$ we can tune $\Delta \omega$ which was predicted to affect drastically the reflected intensity from a phase conjugation mirror for a certain parameter range.

It is our pleasure to thank J. Cserti, R. Fleischmann, C. Lambert and H. Schomerus, for useful discussions. T.K. acknowledges the officers of the 5th A Artillery Unit for their support. This research was supported by a grant from the GIF, the German-Israeli Foundation for Scientific Research and Development.

FIG. 4: The distribution $\mathcal{P}(E_1)$ for a hybrid structure where the normal part is a Fibonacci system with $L = 987$ and $M = 50$ and $V = 1.4$ (o). Overplotted ($\ast$) is the corresponding distribution $\mathcal{P}(E_1)$ for the same Fibonacci system disconnected from a superconductor.
