Background: Obesity causes several health complications along with disruption of the reproductive system. The aim of the current study was to determine how long-term intake of very high fat diet (VHFD) changes the hormonal milieu, affecting the cellular morphology and reproductive cycle in female mice.

Material/Methods: Mice were fed on normal diet (ND) and VHFD for 2 weeks, 12 weeks, and 25–27 weeks. We assessed changes in body weight, food consumption, energy intake, cellular and tissue morphology, hormonal levels (leptin, insulin, and estradiol), and vaginal smears were performed at various time points to determine the length and cellularity at each stage of the estrous cycle.

Results: Mice fed on VHFD showed a significant increase in weight gain, reduction in food intake, and increase in energy intake compared to animals fed on ND, indicating that the caloric density of the diet is responsible for the differences in weight gain. Hormonal analysis showed hyperleptinemia, hyperinsulinemia, and increases in estrogen levels, along with increases in size of the islet of Langerhans and adipocytes. After 25–27 weeks, all animals fed on VHFD showed complete acyclicity; elongation of phases (e.g., diestrous), skipping of phases (e.g., metestrous), or a combination of both, indicating disruption in the reproductive cycle. Quantitative analysis showed that in the diestrous phase there was a 70% increase in cell count in VHFD compared to animals fed on ND.

Conclusions: The above results show that morphological and hormonal changes caused by VHFD probably act via negative feedback to the hypothalamic-pituitary axis to shut down reproduction, which has a direct effect on the estrous cycle, causing acyclicity in mice.

Background

Obesity has become a worldwide epidemic [1,2]. The World Health Organization (WHO) estimated that approximately 1.1 billion people globally are overweight and 320 million are obese [3]. Obesity is not limited to adults; childhood obesity has been increasing exponentially and has become a major concern in most developed countries [4,5]. Obesity is associated with many health complications and diseases, including type 2 diabetes, stroke, heart disease, hypertension, and cancer [6]. The primary cause of obesity is energy intake greater than energy expenditure [7,8]. Energy intake can be increased by consuming larger portion sizes, and energy-dense foods (foods high in sodium, fat, and sugar) [9]. There are also several studies that have shown that diet composition, particularly high dietary fat intake, promotes obesity in humans [10,11] and mice [7].

Recent studies have shown that obesity can cause disruptions in the reproductive system [12–14]. Childhood obesity causes increased risk of menstrual disorders at adolescence [15]. Women with obesity are more likely to have menstrual irregularities and higher risk of miscarriages [12,16]. Distinct changes in circulating hormones like leptin and insulin appear to underlie these abnormalities and are associated with disorders related to feeding and reproduction. Leptin, a hormone secreted from adipose tissue, inhibits food intake, regulates reproduction, and controls homeostasis [17–19]. In the absence of an active form of leptin, rodents are usually hyperphagic, obese, have overactive neuropeptide Y (NPY) neurons, and are fertile [20–22]. Similar maladies are seen in women with chronically low circulating leptin levels, including menstrual abnormalities and reproductive failure [23]. Lower leptin levels are also seen in anovulatory and normal-weight amenorrheic females [24]. Similar to leptin, insulin, a hormone secreted by the pancreas, is also associated with obesity and reproduction [25–27]. Insulin resistance causes reproductive infertility [28,29].

The role of the hypothalamic-pituitary-gonadal (hpG) axis in the development and regulation of the reproductive system is tremendous. Gonadotropin-releasing hormone (GnRH), a hormone released from the hypothalamus, travels down to the anterior pituitary to regulate the production of 2 hormones: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH then act on the ovaries to produce estrogen and progesterone, which are used to regulate the menstrual and ovarian cycles [30,31]. Increases in body weight lead to changes in the release of gonadotropins and gonadal hormones [13,32].

Females go through a menstrual cycle that lasts 28±2 days but for mice an estrous cycle is typically 4–5 days in length. The estrous cycle is distinguished by 4 different phases: proestrus, estrus, metestrus, and diestrus. Each phase is characterized by the presence of different types of cells (nucleated, cornified, leukocytes, or a combination of all 3 cells). Vaginal smears can be used to monitor the stages of the estrous cycle [33].

The current study aimed to determine whether prolonged use of VHFD, which affects the body weight, energy consumption, cellular, and tissue morphology and hormonal profile, also results in changes in the reproductive cycle in female mice. This would help to understand whether prolonged intake of a HF diet can lead to reproductive disorders in women.

Material and Methods

Animals and diet

Fourteen wild-type (C57BL/6J) female mice, age 14-16 weeks, were randomly divided to receive either normal diet (ND, n=6) or VHFD (n=8). The ND consisted of 62% kcal carbohydrate, 25% kcal protein, 13% kcal fat, and 3.07 kcal/g energy density (Rodent Diet 20 5053, Pico Lab). The VHFD consisted of 20% kcal carbohydrate, 20% kcal protein, 60% kcal fat, and 5.24 kcal/gm energy density (D12492, Research Diets). Animals were housed individually in a colony room, with a partially reversed light cycle of 14:10 (lights on at 2300 h and lights off at 1300 h), room temperature 21–22°C (70–72°F), humidity 40–50%, and ad libitum access to food and water. Animals were fed for 25–27 weeks. Body weights were recorded daily with a digital electronic balance for 24 weeks. Food consumption was estimated at the end of 2 weeks, 12 weeks, and 24 weeks by providing pre-weighed food on a specific day and subtracting the weight of the left-over food on that day. Body weights and food consumption were not measured after 24 weeks because animals were decapitated on different days depending on the completion of the estrous cycle. All animal protocols were approved by the Institutional Animal Care and Use Committee at Adelphi University and studies were conducted in accordance with the Guide for the Care and Use of Experimental Animals.

Assessment of estrous cycle

The progression of the estrous cycle was assessed by vaginal smears after female mice were fed on ND or VHFD for 2 weeks, 12 weeks, and 25–27 weeks. Since animals on VHFD showed elongation of estrous cycle, vaginal smears were performed until all animals completed the estrous cycle (starting and ending at the same phase). The entire cycle was repeated to verify the length of the cycle. Since VHFD animals were cycling differently, a 2-week period was required to complete the whole process. Smears were performed at between 11:00 am and 12:00 noon. By inserting the tip into the mouse vagina, vaginal secretions were collected with a plastic pipette.
filled with 10 µl of normal saline (0.9% NaCl). The process was done carefully so that the pipette is not inserted too deep in the vagina, which could cause cervical stimulation and result in pseudopregnancy [34,35]. Saline was quickly released and immediately drawn back into the syringe.

The vaginal smear containing cells was placed on an untreated glass microscopic slide and viewed at 200× and 400× magnification. The stage within the estrous cycle was determined, number of cells quantified, and images were taken using a Spot Insight camera mounted on a Zeiss microscope (Axioskop, Germany). The Papanicolaou (PAP) staining kit (Thermo Electron Corp., Pittsburg, PA) was used to stain the vaginal smear using the methodology suggested by the manufacturer. An average of the cycles was used to quantify the different cell populations at each stage of the estrous cycle. Ten random fields per slide were viewed and counted for nucleated, leukocytic, and cornified cells.

**Biopsy of different organs**

Tissue of appropriate size was dissected out and wrapped in lens paper, marked with a pencil, and placed in formalin overnight. The next day, tissues were placed in cassettes and dipped again in formalin and then sent to Cross Island Laboratories for biopsy. Representative sections were taken from the pancreas (5×3×2 mm) and adipose tissue (1×1×0.5 cm) and photographed at 200×.

**Statistical analysis**

Statistical analysis was done to compare variables among ND and VHFD animals using ANOVA (JMP software, version 7, SAS Institute Inc., Cary, NC). Results are presented as average ±SEM. Effects were considered significant at p<0.05.

**Results**

**Changes in the body weight**

There was an increase in the body weight for both ND and VHFD mice during the time period studied (Figure 1). The weight gain was much greater in VHFD than in ND mice (p<0.0001, 24 weeks). Animals fed on a ND showed an average 8% increase and VHFD mice showed an increase of about 105% of body weight over a period of 24 weeks.

**Food consumption and energy intake**

VHFD animals showed lower food intake when compared to ND animals (Table 1). However, total energy intake by animals on VHFD was significantly higher than in ND mice at both 12 and 24 weeks. The total protein energy intakes in VHFD at all time points were similar. However, the intake of energy from fat was significantly higher in VHFD animals. The energy

---

**Figure 1.** Changes in the body weight when mice were fed on Normal diet (ND) and Very high-fat diet (VHFD) for 24 weeks. Values are average ±SEM.
intake from carbohydrates was significantly higher in ND than in VHFD mice (Table 1).

**Leptin, insulin, and estradiol levels in different mouse models**

Serum leptin, insulin, and estradiol levels were measured at 25–27 weeks of age. As shown in Table 2, leptin, insulin, and estrogen levels were significantly higher in VHFD mice compared to ND mice. The increases were about 8-, 10-, and 2-fold for leptin, insulin and, estradiol levels, respectively, in VHFD fed animals compared to ND.

**Pathomorphological changes**

a) Pancreas: Light microscopic analysis of pancreatic islets from animals on ND showed circular, oval, or elongated shapes with a thin connective sheath surrounding each islets. No inflammation was observed in animals fed on ND for 25–27 weeks. The islets of VHFD showed marked morphological changes with significant increase in the size (hypertrophy) compared to ND within 25-27 weeks (Figure 2).

b) Adipose: There was increase in the size of adipocytes in VHFD over a period of 25-27 weeks. Microscopic analysis showed adipocytes with nucleus on the side. In VHFD the size of the cell increased significantly with the change in the shape of the cell (Figure 2).

**Changes in the cellular morphology in estrous cycle: qualitative and quantitative assessment**

Mouse fed on ND for 2 weeks, 12 weeks and 25–27 weeks showed 4–5 day cycles (proestrous, estrous, metestrous, diestrous) with proestrous phase showing nucleated cells stained dark purple, granulated nuclei with pink or blue cytoplasm surrounded with a blue rim, estrous phase; pale orange and pink stained cornified cells and leukocytic cells stained blue were visible, metestrous phase; dark blue stained leukocytic cells were usually seen in clusters, diestrous phase; similar profile as that of metestrous but with fewer leukocytic cells (Figure 3).

VHFD fed animals showed all 3 stages in sequence similar to ND fed animals during the first 2 weeks indicating no change. Gradually animals started showing abnormalities in phases. By 25–27 weeks, ND fed animals still showed the 3 phases but VHFD fed mice showed abnormalities in phases; elongation of phases (e.g. diestrous for 4 consecutive days), skipping of phases (e.g. metestrous), or a combination of both indicating

### Table 1. Food intake by mice on Normal diet (ND) and Very high fat diet (VHFD) at various time points.

| Time   | Diet   | Food consumed (g) | Total energy intake (kcal) | Total fat (kcal) | Total protein (kcal) | Total carbohydrates (kcal) |

Values are average ±SEM. Statistical analysis using ANOVA showed the following level of significance between animals fed on ND and corresponding VHFD. Level of significance ** p<0.0001 and * p<0.001.

### Table 2. Hormonal levels of mice fed on Normal diet (ND) and Very high fat diet (VHFD) for 25–27 weeks.

| Hormones | Leptin (ng/ml) | Insulin (pg/ml) | Estradiol (ng/ml) |
|----------|----------------|-----------------|-------------------|
| ND       | 2.2±0.2        | 0.25±0.0        | 0.3±0.0           |
| VHFD     | 16.7±0.7**     | 2.5±0.4**       | 0.5±0.0**         |

Values are average ±SEM. Statistical analysis using ANOVA showed the following level of significance between animals fed on ND and corresponding VHFD. Level of significance ** p<0.0001 and * p<0.001.
disruption in the reproductive cycle (Figure 3). Quantitative cellular counts showed significant elongation of diestrous phase (70% increase in cell count between animals fed on ND and VHFD for 25–27 weeks). By 25–27 weeks the cycles were 7–8 days in VHFD animals compared to the 4-5 days seen in normal cycling animals (Figures 3, 4).

Discussion

This study was undertaken to observe the effects of long term (2 weeks, 12 weeks and 25–27 weeks) use of VHFD on reproductive cycle in a rodent model which was equivalent to human age; 1.25 years (childhood), 7 years (pre-teen) and 17.5 years (teen). The result addresses 3 major points: 1. In female mice, diet-induced obesity (DIO) results in an increase in body weight related to the energy content and not the quantity of food consumed. Reduced amount of food intake in VHFD animals was not able to completely compensate for the increased energy density, so little change in energy intake was observed; 2. Significant increases in the leptin and insulin release was related to the cellular morphology and size (islets of Langerhans and adipose tissue) in VHFD animals; 3. Prolonged feeding of VHFD to female mice results in disruption of the estrous cycle. The regulation of body weight involves diet and genetic make-up [36]. High Fat Diet (HFD) induces an energy surplus that causes obesity [6]. Results indicate that the increase in body weight was not due to the quantity of food intake but due to the high energy content of the food. Mice on HFD showed a broad range of body fat with increases in the leptin levels. The decrease in food consumption in VHFD animals compared to animals on ND could be due to increased leptin and insulin levels [37,38]. However, the energy intake was not affected by the increases in the hormonal level. It appears that leptin suppresses the amount of food intake but has little effect on the caloric intake.
The reproductive cycles in humans or the estrous cycle in mice are both under the influence of the hpg axis [39,40]. The effects are most drastic during puberty. The increase in estrogen in VHFD mice could be due to an increase in the adipose tissue, which produces aromatase and thereby increases the conversion of testosterone to estradiol [41]. Long-term obesity leads to decreased hepatic inactivation by estrogen 2-hydroxylation, which also causes increases in estradiol levels in blood.

**Figure 3.** Representative animals showing cellular changes across the estrous cycle on ND and VHFD for 2 weeks (1st and 2nd column), and 25–27 weeks (3rd and 4th column). Stages of estrous Cycle, metestrous – M, diestrous – D, proestrous – P, and estrous – E. Cells in the different phases of the estrous cycle are denoted by nucleated cells – N, cornified cells – C, and leukocytic cells – L at 400× magnification. Elongation of phases in VHFD animals and repeated diestrous phase are indicative of the disruption of estrous cycle.
Moreover, the adiposinsular axis may be affected by the increases in size of adipose and islet size, which leads to increases in the release of insulin and leptin, causing lowering of sex hormone-binding protein levels, resulting in increased bio-availability of estrogen in blood [42,43]. In rats, DIO results in lack of LH surge [44] along with reduced LH levels after treatment with HF for 180 days. It has also been reported that the levels of progesterone are increased when rats are treated with HFD for 180 days [45]. Thus, it appears that decreases in the adipose and islet morphology and size, which results in increased bio-availability of estrogen in blood [42,43]. In rats, DIO results in lack of LH surge [44] along with reduced LH levels after treatment with HF for 180 days [45]. Thus, it appears that decreases in the LH levels with reduced LH surge in conjunction with increased progesterone and estradiol levels results in the elongation of estrous cycle and acyclicity, leading to reduced reproductive function. Once these changes have occurred, even reversing the diet from HF to ND does not change the reproductive capacity, although several metabolic parameters may return to normal levels [46]. This shows that the adverse effects of HF are more severe and irreparable in reproductive tissues than any other affected tissues.

Leptin acts as a metabolic factor linking fat with reproduction. Leptin has been linked with multiple factors that lead to pulsatile release of GnRH [47]. When the levels of leptin are chronically high, the actions of leptin on reproduction are probably disrupted. This may be due to impaired flow of leptin through the blood-brain barrier [48] or perhaps the lower expression of leptin receptor or leptin itself causes ‘leptin-induced leptin resistance’. All of the above factors reduce the availability of leptin in the CNS, affecting the hypothalamus, which in turn affects the release of GnRH, damping the cyclicity. Our previous research [39,49] has shown that ob/ob mice lacking leptin and Agouti mice with chronically high leptin levels are acyclic, and our current study shows that animals fed with VHFD develop chronically high leptin levels and are also acyclic. These results suggest that leptin is required in optimal concentrations but is not the sole determining factor for reproduction.

Leptin and insulin together have been implicated in GnRH secretion [50,51]. We therefore speculate that when insulin is produced in chronically high amounts (hyperinsulinemia), it probably causes GnRH to release tonically or causes an increase in pulsatility, both of which can disrupt the reproductive cycle. Further, chronic hyperstimulation causes a decreased biosynthetic capacity, which also can result in acyclicity and disruption of the estrous cycle.

**Conclusions**

Taken together, it seems that mice on an HF diet undergo changes in the adipose and islet morphology and size, which results in release of chronically high levels of insulin and leptin. This results in changes in the hpg and adiposinsular axis, causing disruption in the LH surge and resulting in changes in the secretion of gonadal hormones. These changes in the hormonal milieu have a direct effect on the estrous cycle, causing disruption of the cycle. Thus, we can conclude that prolonged intake of VHFD changes several biochemical parameters and has a drastic effect on the reproductive cycle, affecting fertility. The effects of a high-fat diet on reproductive tissues are irreversible and irreparable.
