Abstract
Oil–water two-phase flow in horizontal oil-producing wells with low velocity and high water cut generally presents the phenomenon that the underlayer shows water flow and the upperlayer presents oil flow or a dispersion of oil in water flow. And existing ring-shaped conductance water cut meter cannot obtain the online and real-time response values corresponding to oil field water conductivity in the calculating water holdup procedure. To tackle this issue, this paper designs a mini-conductance probe array (MCPA). In order to further investigate the ability of the total flow rate of the allowable measurement fluid and the parameters valuing of the water cut in horizontal segregated flow, this paper also analyzes the performance of MCPA with different structure parameters in terms of the spatial sensitivity distribution characteristics. Firstly, the geometry model and mathematical model of MCPA are designed, and the MCPA simulation model is analyzed by using the finite element method. Then, the optimum structure parameter results of the sensors are obtained through analyzing the spatial sensitivity distribution characteristics of MCPA in consideration of different distance between the two electrodes and different inner diameters. Lastly, the MCPA different parameters are developed, and experiments are carried out in horizontal multiphase flow experiment facility to analyze spatial sensitivity distribution characteristics of MCPA with different inner diameters on the basis of optimum parameters. Experimental results demonstrated that MCPA with a larger inner diameter would have high measurement accuracy in variation range of water cut, and has a high adaptability in horizontal oil-producing wells with relatively high flow rate and different flow conditions.

Keywords
Horizontal oil–water two-phase flow · Segregated flow · Mini-conductance probe array · Control-drive circuit · Water holdup

Introduction
Horizontal two-phase flow is widespread in the petroleum industry, chemical engineering, pharmacy and nuclear reaction, etc. In particular, with the rapid development of horizontal well technology, the accurate measurements for the phase volume fraction (liquid holdup) and production rate of each component at any production layer in oil–water two-phase flow are very significant for the oil development and the oil production optimization (Li et al. 2016). In particular, the water cut of the whole oil-producing well would increase sharply when the partial well sections are flooded in the process of horizontal well production and development. And it would have a negative impact on development effectiveness of horizontal oil-producing wells, and even cause the disuse of oil-producing wells (Zhai et al. 2012a, b; Kong et al. 2015). Hence in order to improve the horizontal oil field logging techniques and optimize the oil production, horizontal production profile logging data interpretation is becoming an important research hotspot in the related research fields. Consequently, water cut, as an important and representative indicator, needs to be acquired as accurate as possible (Li et al. 2016; Feng et al. 2018).

In the investigations on the flow patterns of horizontal oil–water two-phase flow patterns, experimental and theoretical study in a horizontal pipe with the inner diameter...
of 50.1 mm was comprehensively performed by Trallero et al. (1996), and then the flow patterns are classified into segregated flow and dispersed flow; an experiment on the flow patterns under oil–water two-phase conditions in a large inner diameter horizontal pipe was conducted by Yang et al. (2008), and the same result of flow patterns classification is obtained. Hence, in the actual horizontal oil wells with long distance undulating, a mixed flow pattern, which is mainly horizontal segregated flow, whose phenomenon that the underlayer shows a water flow and the upperlayer shows an oil flow or a dispersion of oil in water, exists in the horizontal oil–water two-phase flow with low velocity and high water cut, compared to vertical wells, and flow pattern and velocity are greatly influenced by the inclination of horizontal oil-producing wells (Trallero et al. 1996; Lum et al. 2006); so the most previous profile parameters measurement instruments for the production of vertical wells cannot be directly used for horizontal oil-producing wells (Guo et al. 2009). And it can be deduced that the various complicated flow structures in horizontal oil–water two-phase flows raise many challenges in the profile parameter measuring sensor design.

The conductance sensor with special structure and characteristic is applicable to more complex environmental conditions and different fields (Asali et al. 1985; Wang et al. 2016). In particular, the ring-shaped electrodes conductance sensor has almost no disturbance to fluid and then could be widely used in vertical upward two-phase flow (Lucas et al. 2000; Devia and Fossa 2003; Jin et al. 2008; Shi et al. 2010). The measurement principle of the conductance sensor indicates that water cut can be determined by oil–water mixture conductivity and water conductivity. In horizontal oil-producing wells, the response values corresponding to the oil–water mixture conductivity could be measured online in the process of fluid flowing by using the ring-shaped conductance probe (RSCP) (Zhai et al. 2012a, b). However, due to the structure characteristics of the horizontal oil-producing wells and structure limitations of the ring-shaped conductance water cut meter (RSCWCM), the electrodes of RSCP must still be immersed in the oil–water segregated flow in whole sampling procedure so that the online and real-time response values corresponding to the oil field water conductivity.

Considering that the values of the structure parameters would influence the uniformity of the spatial sensitivity directly, this paper analyzes and discusses the characteristics of the spatial sensitivity in the measurement field of MCPA from the aspects of the different electrodes separations and different inner diameters of the insulated flow pipe and ability of the allowable total flow rate of the fluid and the values of the water holdup parameters in the condition of horizontal segregated flow, on the basis of the conductance sensor for water conductivity measurement in horizontal oil–water two-phase flow (Kong et al. 2016b, 2017). Then, the response characteristics of water conductivity measurement of MCPA with different inner diameters are analyzed by the simulation experiments and simulation wells experiments in horizontal oil water two-phase flow on the foundation of the structure parameter optimization.

Model and simulation of MCPA

Geometry model

Figure 1 shows the geometry of MCPA. MCPA consists of six pairs of metal parallel electrodes, in which each pair of metal parallel electrodes is a mini-conductance probe (MCP), and serves as the exciting electrode and the measuring electrode along the axial direction. In addition, one end of each electrode is flush-mounted on the inside wall of the insulated flow pipe, six electrodes represented by $E_1$ to $E_6$ are homogeneously distributed on the same upstream cross section along the axial direction, and six electrodes represented by $M_1$ to $M_6$ are homogeneously distributed on the same downstream cross section along the axial direction. Each pair of $E_i$ and $M_i$ electrodes forms the $i$th mini-conductance probe (MCP$_i$), where $i$ ranges from 1 to 6.

MCP$_1$ is located at different locations in the space of the insulated flow pipe, where MCP$_1$ is located at the bottom of the insulated flow pipe, MCP$_4$ is located at the top of the insulated flow pipe, MCP$_2$ and MCP$_6$ are located at the same height of

![Fig. 1 Sketch of MCPA geometry model](image-url)
the insulated flow pipe, MCP₂ and MCP₃ are located at the same height of the insulated flow pipe.

The representative structure parameters and the coordinates of MCPA are shown in Fig. 2, in which S is the distance between two electrodes of MCP, d is the diameter of each metal parallel electrode, h is the measurement field height of the metal parallel electrode, D is the inner diameter of the insulated flow pipe, Dᵢ is the thickness of the insulated flow pipe, and L is the axial length of the insulated flow pipe.

**Mathematical model**

In order to reduce or inhibit the leakage current in the flow field, the design of MCPA system drive circuit introduced the real ground (the earth or shell of instrument) and imaginary ground, that is, the sensor electrode excitation is carried out by the digital ground power supply uₛ₉ and the sensor output signal used analog power supply uₛ_digt for different amplifiers, since the voltage reference point uₛ₉ of the exited part and the uₛ_digt of the measured part are isolated from each other, which means that corresponding to real ground uₛ₉ = 0 as the shell of instrument, the measurement pipes internal fluid of MCPA have independent electric field and electric potential, which also has digital ground uₛ_digt = 0 as the reference point.

Since the measurement field of MCPA is much smaller than the wavelength of the electric field, the electric field of MCPA can be considered as quasi-stationary electric field, which can be described with the theory of the static electric field, that is, meeting the Laplace equation with some certain boundary conditions under the cylindrical coordinates (Yang et al. 2008; Zhai et al. 2012a, b):

\[
\nabla^2 u_{\text{digt}}(r, \varphi, z) = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial u_{\text{digt}}}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 u_{\text{digt}}}{\partial \varphi^2} + \frac{\partial^2 u_{\text{digt}}}{\partial z^2} = 0
\]

(1)

and each MCPᵢ of MCPA is constrained by the essential boundary conditions, which can be expressed as:

\[
\begin{align*}
    u_{\text{digt}} &= 0, \quad (r \in [D_2 - h, D_2/2], \varphi \in [i - 1/3 \pi - \arctan\left( \frac{d}{D_2 - 2h} \right), i - 1/3 \pi + \arctan\left( \frac{d}{D_2 - 2h} \right)], S - d/2 \leq z \leq S + d/2) \\
    \frac{\partial u_{\text{digt}}}{\partial r} &= \frac{I_e}{S_d}, \quad (r \in [D_2 - h, D_2/2], \varphi \in [i - 1/3 \pi - \arctan\left( \frac{d}{D_2 - 2h} \right), i - 1/3 \pi + \arctan\left( \frac{d}{D_2 - 2h} \right)], -S + d/2 \leq z \leq -S - d/2)
\end{align*}
\]

(2a)

(2b)

\[
\frac{\partial u_{\text{digt}}}{\partial z} = 0, \quad (z = \pm L/2)
\]

(2c)

where uₛ_digt is the internal electric potential distribution of MCPA, Iₑ represents the direct current applied to exciting electrodes, D is the ID of the insulated flow pipe, L is the axial length of the insulated flow pipe, and S_d is the surface area of the electrodes of MCPᵢ.

**Simulation analysis for electric field**

The finite element simulation was employed to analyze the distribution characteristics of the inner electric field of MCPA. Figure 3 shows the three-dimensional simulation

**Fig. 2** Sketches of structure parameters and coordinates of MCPA: a axial section; b cross section
The sectional views of the electric field distribution of MCPA are shown in Fig. 4. Figure 4a shows the electric field distributions of MCP1 and MCP4 in the YoZ cross section of MCPA. Analyzed from Fig. 4a, the electric field is relatively strong around the two electrodes of MCP1 and MCP4, respectively, and the electric field in the area far from the electrodes is relatively weak, toward the value of zero. And the top MCP4 and the bottom MCP1 in the YoZ cross section generate a relatively strong local electric field, which is relatively independent and non-interference. Figure 4b shows the electric field distributions of MCP1 in the XoZ cross section of MCPA. In the XoZ section, there exists a relatively strong local electric field around the two electrodes of MCP1, and the local electric field far from the electrodes is relatively weak, even to 0. Figure 4c shows the electric field distributions of the MCP1 in the XoY section of MCPA. In Fig. 4c, the six separate local electric fields are distributed uniform at the different positions of the XoY cross section, and independent of each other.

Analysis on the spatial sensitivity of MCPA

Sensitivity characteristics are important performance indicators of conductance sensor. When conducting the oil–water two-phase flow measurement under the downhole, to reduce the impact of flow patterns, the conductance sensor is needed to be designed as sensitivity uniformly distributed (Gao et al. 2010). This paper processed the normalization on the parameter \( H \), which is \( Y \)-axis location of the center of mass of the insulated oil droplet (the diameter is 2 mm) in the sensitive space of the MCPA whose inner diameter is \( D \), the result of which can be expressed as \( H/D \). And the \( H/D \) ranges from \( 1/D \) to \( 1 - 1/D \). Then, the finite element model can be solved by changing the location \((x, H/D, z)\) of the center of mass of the insulated oil droplet in the sensitive space. And then, the distribution characteristic of the spatial sensitivity can be obtained.

Taking into account that the parameter \( S \) is one of the main factors influencing the uniformity of the sensitivity field distribution in MCPA measurement field and that parameter \( D \) can determine the stability of the water conductivity measurement in certain horizontal segregated flow with size-fixed flow rate and water cut, the structure parameters were optimized using different \( h \) values under the condition that \( D = 20 \) mm in the early work, and the optimum structure parameters of different \( h \) values can be obtained using the uniformity of both the electric field and the spatial sensitivity. Hence, the effect of different values of the parameters \( S \) and \( D \) on the spatial sensitivity distribution characteristics of MCPA was discussed, taking MCP1, composed of the \( E_i \) and \( M_i \), at the bottom of the insulated flow pipe, as the example, when \( h = 2 \) mm, \( d = 1.5 \) mm and the oil conductivity \( \sigma_o \) is \( 10^{-9} \) μS/cm.

The effect of different values of parameter \( S \)

Specifying \( D = 20 \) mm, the spatial sensitivity characteristics of MCP1 measurement area are further discussed and analyzed in three different conditions that parameter \( S \) is set to 4 mm, 5 mm and 6 mm, respectively. Figure 5 shows the spatial sensitivity distribution characteristics in the YoZ plane, along the Z-axis direction and along the Y-axis direction, under different \( S \) values. It can be known from the spatial sensitivity distribution in the YoZ plane that a large difference exists at the different locations in the YoZ plane under
the different $S$ values and the spatial sensitivity in the vicinity of measurement field is relatively high, and the spatial sensitivity away from the electrodes is relatively low and tends to be 0. And it can be analyzed from the Z-axis direction that the spatial sensitivity distribution of MCP1 along the Z-axis direction is greatly influenced by the parameter $S$ and with the parameter $S$ increases, the uniformity of the spatial sensitivity distribution reduces in the measurement field between the two electrodes of MCP1. So the spatial sensitivity distribution is more uniform when $S = 4$ mm. It can be analyzed from the Y-axis direction that the spatial sensitivity distributions of MCP1 are basically consistent at different locations along the Y-axis direction. And with the increase in the $H/D$, the spatial sensitivity under different $S$ values gets smaller, especially falls at a high rate and demonstrates high gradient descent in the interval $(1/20, 6/20)$ and shows a slow change of the spatial sensitivity and tends to be 0 in the interval $(6/20, 19/20)$.

To further discuss the influence of different $S$ values on the spatial sensitivity distribution characteristic in the condition of the insulated flow pipe with $D = 20$ mm, the results of the sensitivity distribution curves along the Y-axis at the location that $z = 0$ under different $S$ values are shown in Fig. 6. It can be known that with the increase in $H/D$, the values of the spatial sensitivity under different $S$ values show a decreasing tendency, and the sensitivity distribution curve firstly tends to be the minimum value when $S = 4$ mm. Simultaneously, the spatial sensitivity of MCP1 is large, falls

![Fig. 5 Distribution maps of spatial sensitivity of MCP1 under three different $S$ values: $D = 20$ mm, $h = 2$ mm and $d = 1.5$ mm](image-url)
fast, and demonstrates a high gradient, which shows that the measurement signals of MCP are greatly influenced by the oil droplet when \( H/D \) is located in the \((1/20, 6/20)\); the sensitivity changes slowly and tends to be the minimum value when \( H/D \) is located in the \((6/20, 19/20)\), which shows that the measurement signals of MCP are almost not influenced by the oil droplet and even never influenced in the interval.

From the above analysis, the spatial sensitivity distribution of MCP is more uniform when \( S = 4 \text{ mm} \) in the condition of the insulated flow pipe with \( D = 20 \text{ mm} \). And the sensitivity distribution of MCP along the \( Y \)-axis is gently influenced by the parameter \( S \) and the measurement signals of MCP are slightly or even not influenced by the insulated oil droplet or the non-conductive materials in the interval of \( H/D \in (6/20, 19/20) \). Hence, in that condition, a more reliable water phase calibration value can be obtained.

### The effect of different values of parameter \( D \)

The parameter \( S \) after optimization is \( 4 \text{ mm} \) when \( D = 20 \text{ mm} \), \( h = 2 \text{ mm} \), \( d = 1.5 \text{ mm} \). Hence, the effect of parameter \( D \) valued \( 20 \text{ mm}, 30 \text{ mm}, 40 \text{ mm}, 50 \text{ mm}, 60 \text{ mm} \) and \( 70 \text{ mm} \) was analyzed and discussed, respectively, on the spatial sensitivity of MCP in the measurement field under the condition of certain values of the parameters \( h, d \) and \( S \). Figure 7 shows the spatial sensitivity distribution characteristics of MCP in the YoZ plane, along the \( Z \)-axis direction and along the \( Y \)-axis direction, under different \( D \) values. It can be known from the sensitivity distribution in the YoZ plane that the sensitivity distributions in the YoZ plane under six different \( D \) values are basically consistent which shows a large difference in the spatial sensitivity in the measurement field. The spatial sensitivity in the vicinity of the measurement field between the two electrodes is higher and that away from the measurement field is lower and tends to be 0. It can be known from the spatial sensitivity distribution along the \( Z \)-axis that the spatial sensitivity distributions along the \( Z \)-axis under six different \( D \) values are basically consistent which is hardly influenced by the parameter \( D \) and that the spatial sensitivity in the vicinity of the two electrodes is more uniform. It can be known from the sensitivity distribution along the \( Y \)-axis that the sensitivity distributions along the \( Y \)-axis under six different \( D \) values are basically consistent which shows a decreasing tendency and that the spatial sensitivity under six different \( D \) values is higher, changes fast and has a great gradient descent in the interval of \((1/20, 6/20), (1/30, 6/30), (1/40, 6/40), (1/50, 6/50), (1/60, 6/60) \text{ and } (1/70, 6/70) \), respectively. And it can also be known that the spatial sensitivity in the interval of \((6/20, 19/20), (6/30, 29/30), (6/40, 39/40), (6/50, 49/50), (6/60, 59/60) \text{ and } (6/70, 69/70) \) is lower and tends to be 0.

To further investigate the effect of the six different \( D \) values on the spatial sensitivity characteristic of MCP, the curves of the spatial sensitivity distribution with six different \( D \) values along the \( Y \)-axis at the position that \( z = 0 \) are shown in Fig. 8. It can be seen from the curves that with the increase in the \( H/D \), the spatial sensitivity distribution of MCP with six different \( D \) values along the \( Y \)-axis shows a decreasing tendency and simultaneously the spatial sensitivity under six different \( D \) values is higher, changes fast and has a great gradient descent in the interval of \((1/20, 6/20), (1/30, 6/30), (1/40, 6/40), (1/50, 6/50), (1/60, 6/60) \text{ and } (1/70, 6/70) \), respectively, which shows MCP is greatly influenced by the insulated oil droplet in the measurement field. And it can be also known that the spatial sensitivity changes slowly and tends to be 0 when the \( H/D \) is in the interval of \((6/20, 19/20), (6/30, 29/30), (6/40, 39/40), (6/50, 49/50), (6/60, 59/60) \text{ and } (7/70, 69/70) \) which shows that the spatial sensitivity of MCP is slightly influenced by the insulated oil droplet in the measurement field.

From the above analysis, the spatial sensitivity distributions corresponding to the six different \( D \) values of the insulated flow pipe in the YoZ plane and that along the \( Z \)-axis are basically consistent. It can be analyzed that the variation range of the spatial sensitivity of MCP with six different \( D \) values of the insulated flow pipe when \( H/D \in (1 \text{ mm}/D, 6 \text{ mm}/D) \) is from 1 to 0.1, falls fast and show a large gradient descent and that when \( H/D \in (6 \text{ mm}/D, (D−1 \text{ mm})/D) \) changes slowly and tends to be 0. Consequently, in the condition with six different \( D \) values of the insulated flow pipe, the influence on the actual measurement signals of MCP from the insulated oil droplet and non-conductive materials is small and tends to be 0, where the reliable water conductivity measurement signals can be obtained.
Analysis of experiment results in horizontal oil-water two-phase flow

On the above basis of the analyzed spatial sensitivity characteristics of the sensors with different structure parameters, the response characteristics of MCPA with three different $D$ values in horizontal oil-water flow were analyzed by the simulation well experiment, where the structure parameters after the optimization of MCPA are set that $h=2\text{ mm}$, $d=1.5\text{ mm}$ and $S=4\text{ mm}$, the three different $D$ values are 20, 30 and 50 mm, and MCP$_1$ $\sim$ MCP$_6$ are corresponding to the six groups conductance sensors. After consulting the relevant literature and information, owing that the oil phase is considered as the non-conductive material and has no conductive property, and the oil belongs to low-conductivity material. And it can be known from the water and oil conductive property that the water conductivity $\sigma_w$ is greater than the oil–water mixture conductivity $\sigma_m$, and the $\sigma_m$ is larger than the oil conductivity $\sigma_o$. Hence, in horizontal oil-water flow with high water cut, the response signals with the minimum amplitude, which can be considered as the water phase calibration signals, can be obtained by the bottom location of the cross section of MCPA insulated flow pipe, that is, the location of MCP$_1$.

Owing that the ratio of the oil–water contact interface height of MCPA insulated flow pipe cross-section $H_w$ and the parameter $D$ is $H_w/D=(1-\cos\alpha)/2$ and $\alpha$ is the corresponding central angle, the range of the $H_w/D$ is...
The relation between the water cut $y_m$ and $H_w/D$ is nonlinear. When $y_m = 1$ or $H_w/D = 1$, the fluid in the insulated flow pipe shows a water phase; and when $y_m = 0$ or $H_w/D = 0$, the fluid in the insulated flow pipe shows an oil phase. In addition, the fluid in the insulated flow pipe shows an oil–water mixture phase and the response values of the sensors are corresponding to the oil–water mixture conductivity under the condition that $0 < y_m < 1$ or $0 < H_w/D < 1$.

**Experimental facility**

taking a new scheme with the introduction of digital power supply and analog power supply isolation system using the A_S-XWR&B_LS-XWR series, and the integrated circuit constructed by ICL8038 and peripheral components as the 20 kHz sinusoidal exciting source with the introduction of digital power supply system, the integrated circuit constructed by AD620 and peripheral components as the differential operational amplifier, low-pass filter and signal demodulator with the analog power supply system to process the alternating current signal generated by the measuring electrodes, the integrated circuit AD637 as the RMS to DC conversion measurement circuit to avoid the voltage loss on the long-distance transmission. And the integrated multiplex programmable analog switch circuit mainly consists of the microcontroller STM32FXXX series and single 8-channel analog multiplexer CD4051 using the introduction of digital power supply. All the electronic components involved in Fig. 10 are selected as military level. And the working temperature condition of the designed MCPA system prototype is in −55–125℃ and the overall pressure resistance is 30 Mpa, meeting the downhole complex environment requirements of the high temperature and high pressure in the practical logging.

The data acquisition equipment is selected from the Yan-shan University’s independent development product: the composite signal frequency measurement system, which is based on the USB 2.0 port. Equipped with three sampling channels and selector switch, the data processing part is implemented through graphical programming language software for MFC, which can make real-time frequency data waveform displaying, storing, reviewing and analyzing, as is shown in Fig. 11.

The instrument output is expressed by the frequency signal \( F_m (KHz) \) which can be described as:

\[
F_m = k_m \times V_m \times 10^{-3}
\]

where \( k_m \) is the correction coefficient of the linearity conversion, \( V_m \) is the output voltage of the measurement electrodes.

Figure 12 shows the photos of MCPA with three different inner diameters and the gold-plated electrode with \( h = 2 \text{ mm} \) and \( d = 1.5 \text{ mm} \). The experimental media were tap water and industrial white oil. In the experiment, the fluid is forced into the insulated flow pipe of MCPA with \( D = 20 \text{ mm}, 30 \text{ mm} \) and \( 50 \text{ mm} \), respectively, from a large diameter horizontal plexiglass pipe. The response values of both the \( y_m \) and \( H_w/D \) can be obtained corresponding to the different flow conditions by changing the oil cut of the oil–water mixture.

**Static experiment**

Figure 13 shows the frequency response curves with three different \( D \) values in horizontal segregated flow under different values of \( y_m \) and \( H_w/D \), respectively. It can be seen from Fig. 13 with the increase in the \( y_m \) or \( H_w/D \), the response value \( F_m \) of the MCP1 with three different \( D \) values becomes small and tends to be the response values corresponding to the water conductivity. It can be known from Fig. 13a that the frequency response values of MCP1 with three different \( D \) values is larger and the rate of change is fast when \( y_m < 5/D \) (when \( D = 20 \text{ mm}, y_m < 0.25 \) ), which shows that the sensors with different \( D \) values in that condition are seriously influenced by the oil phase. It can be also known that the frequency response values of MCP1 with three different \( D \) values is relative stable and approximate to the response values corresponding to the water conductivity when \( y_m > 5/D \), which shows that the sensors with different \( D \) values in that condition are hardly influenced by the oil phase and the response values obtained can be used as the calibrated values for the water phase. It can be known from Fig. 13b that the frequency response values of MCP1 with three different \( D \) values is larger and the change rate is fast when \( H_w/D < 6/D \) (when
D = 20 mm, \( H_w/D < 0.3 \), which shows that the sensors with different \( D \) values in that condition are seriously influenced by the oil phase. It can be also known that the frequency response values of MCP1 with three different \( D \) values is relatively stable and approximate to the response values corresponding to the water conductivity when \( H_w/D > 6/D \), which shows that the sensors with different \( D \) values in that condition are hardly influenced by the oil phase and the response values obtained can be used as the calibrated value for the water phase. And simultaneously, when \( D = 50 \) mm, the sensor can obtain a stable calibrated value corresponding to the water conductivity in the condition that \( y_m > 5/50 \) or \( H_w/D > 6/50 \).

From the above analysis, when \( y_m > 5/D \) or \( H_w/D > 6/D \), the response value of MCP1 with three different \( D \) values approximate to the measurement value corresponding to the water conductivity. And simultaneously, with the increase in the inner diameter of the sensor, the critical point of the \( y_m \) where the sensors comes to the stable response values changes from \( 5/20 \) to \( 5/50 \) and the critical point of the \( H_w/D \) where the sensors comes to the stable response values changes from \( 6/20 \) to \( 6/50 \).

**Experiment and analysis under different mineralization degree and temperature**

In order to investigate the response characteristics for the different mineralization degree of water and temperature in the fluid to the three different inner diameters of MCPA and the corresponding linear relation between MCPA with different inner diameters and RSCP with ID = 20 mm, considering the high mineralization degree and high temperature in real oil-producing wells, the paper carried out the experiment...
research on the different mineralization degree of water using three different inner diameters of MCPA and RSCP with high temperature in the simulation well experimental facility. When carrying out the routine mineralization degree calibration, the different values of water salinity $\rho_w$ are used to represent the different mineralization degree of water and $\rho_w = 1.0 \text{ g l}^{-1}$ represents the mineralization degree 1000 ppm. Hence, the response values of the experiment are calculated at the condition of filling with continuous water medium in the insulated pipe under different values of $\rho_w$ in which the range of $\rho_w$ is from 0.5 $\text{ g l}^{-1}$ to 7.5 $\text{ g l}^{-1}$. Figure 14 shows the response values of between MCPA with different inner diameters and RSCP for water medium measurement in terms of different values of $\rho_w$ and different temperature $T_w$, respectively, in horizontal pipe, where $\rho_w$ is set to 0.5 $\text{ g l}^{-1}$, 1.5 $\text{ g l}^{-1}$, 2.5 $\text{ g l}^{-1}$, 3.5 $\text{ g l}^{-1}$, 4.5 $\text{ g l}^{-1}$, 5.5 $\text{ g l}^{-1}$, 6.5 $\text{ g l}^{-1}$, and 7.5 $\text{ g l}^{-1}$, and $T_w$ is set to 40°, 60°, and 80°, respectively. As can be observed from Fig. 14, under the same temperature condition, with the increase in $\rho_w$, the measured frequency results of MCPA with different inner diameters and RSCP show a decreasing tendency and obvious difference which can be attributed to the distinctive difference of $\rho_w$. Under the same mineralization degree condition, with the increase in $T_w$, the measured frequency results of MCPA with different inner diameters and RSCP show a decreasing tendency and obvious difference which can be attributed to the distinctive difference of $T_w$. Meanwhile, the response values of MCPA with different inner diameters exhibit obvious difference. And the response values of the sensor with a larger inner diameter are relatively smaller, which is as a result that the difference in the sensor structure with different inner diameters makes a certain difference existed in the electric field of the corresponding excited electrodes.

According to Fig. 14, it can be observed that MCPA with different inner diameters and RSCP have nice response characteristics for water medium measurement under different values of $\rho_w$ at different high temperatures, respectively. The current loss existed in the system circuits would exhibit a nonlinear change with the change of the fluid component or conductivity inside the sensors, causing the non-constant current in the measurement field of the sensors, which will lead to that the measurement results of MCPA with different inner diameters and RSCP show a nonlinear change under different values of $\rho_w$ at different high temperatures.

Figure 15 shows the fitting curves of experiment results between MCPA with three different inner diameters and

---

**Fig. 14** Response values of conductance probes under different values of $\rho_w$ at different high temperatures: a MCPA with $D = 20$, 30 and 50 mm, respectively, b RSCP with ID = 20 mm.
RSCP. As can be observed from Fig. 15, the abscissa positions corresponding to each discrete point with three different marker symbols represent the response values of RSCP experiment results, and the ordinate positions represent the response values of experiment results of MCPA with different inner diameters at the same condition with RSCP. The continuous curves represent relationship curves of experiment results between MCPA with different inner diameters and RSCP by using the linear fitting. Under the same condition, the response values between MCPA with three different inner diameters and RSCP show a relatively nice linear function relation, and the relation curves can be given as:

\[
\begin{align*}
F_M &= 5.1235F_R + 0.3218 \quad (\rho_w \in (0.5 \text{ g/L}, 7.0 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 20 \text{ mm}) \\
F_M &= 5.0391F_R + 0.1654 \quad (\rho_w \in (0.5 \text{ g/L}, 7.0 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 30 \text{ mm}) \\
F_M &= 3.8095F_R + 0.2821 \quad (\rho_w \in (0.5 \text{ g/L}, 7.0 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 50 \text{ mm})
\end{align*}
\]

where \( F_R \) is the measured frequency of RSCP, \( F_M \) is the measured frequency of MCPA and \( \rho_w \) is the water salinity.

The good and bad points of the fitting curves by the response values of MCPA with different inner diameters and RSCP in different mineralization degree and temperature conditions is measured by the relative index \( R^2 \) of the curve fitting degree (Kong et al. 2016a). According to Eq. (4), the corresponding relative indexes of MCPA with three different inner diameters and RSCP fitting curves in different mineralization degree and temperature conditions can be obtained:

\[
\begin{align*}
R^2 &= 1 - \frac{0.15715073}{28.65421296} = 0.9945 \quad (\rho_w \in (0.5 \text{ g/L}, 7.5 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 20 \text{ mm}) \\
R^2 &= 1 - \frac{0.2453271163}{24.53771163} = 0.9949 \quad (\rho_w \in (0.5 \text{ g/L}, 7.5 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 30 \text{ mm}) \\
R^2 &= 1 - \frac{0.05699746}{14.81896733} = 0.9962 \quad (\rho_w \in (0.5 \text{ g/L}, 7.5 \text{ g/L}), \ T_w \in (40^\circ \text{C}, 80^\circ \text{C}) \text{ and } D = 50 \text{ mm})
\end{align*}
\]

Analyzed from the relative index \( R^2 \), with the change of mineralization degree and temperature, the curve fitting degrees of MCPA values differently, and the corresponding curve has a nice fitting index.
Conclusions

In consideration of the problem that the response values corresponding to the water conductivity cannot be obtained by RSCP for water holdup measurement in horizontal oil–water two-phase flow, the spatial sensitivity distribution of MCPA in the measurement field with different structure parameters $S$ and $D$ was discussed and analyzed, on the theoretical model foundation of MCPA for water conductivity measurement in horizontal segregated flow. And the optimum structure parameters of the sensors for segregated flow measurement are obtained, that is, when $S=4$ mm, the spatial sensitivity is more uniform. The response characteristics of MCPA with different $D$ values was analyzed by the simulation experiments, the spatial sensitivity distribution curve of which and the response values curve show a nice consistency. The experimental results verified that the response characteristics of MCPA with three different $D$ values are basically consistent under different $y_m$ or $H_p$ / $D$ and that the characteristic of MCPA is hardly influenced by the insulated oil phase or non-conductive materials under the condition that $y_m > 5 / D$ or $H_p / D > 6 / D$. And it analyzed response characteristics and indicated good linearity characteristics between the designed MCPA with three different inner diameters and RSCP for pure-water phase measurement with experiments under different mineralization degrees of water and different temperatures. The experiment results of the sensors with three inner diameters in different flow rates show that the sensor with the inner diameter 50 mm is more suitable to the water cut measurement when the flow rate is large, and the reliable calibrated values corresponding to the water conductivity can then be obtained, which meets the demand of horizontal oil-producing wells.
