Abstract
The external carotid artery (ECA) is the major blood supply for structures in the head and neck. Typically, it has eight separate branches; but there are many anatomical variations, making it difficult to predict surgical outcomes and complications without three-dimensional imaging. This case study focuses on a cadaver with multiple anatomical variations in the ECA, i.e., lingual, facial, occipital, ascending pharyngeal, and posterior auricular arteries, found during routine dissection of the right cadaveric neck. We also discuss the incidences of several other anatomical variations of the ECA branches and their surgical implications and potential complications.

Key words: lingofacial trunk, external carotid artery, anatomy, variation, cadaver

INTRODUCTION
The external carotid artery (ECA) forms at the bifurcation of the common carotid artery (CCA) at the level of the fourth cervical vertebra. It has eight major branches that supply areas around the head, neck, and face. It terminates as it bifurcates into the maxillary artery, which supplies the maxillary region and several adjacent regions such as the oral cavity, and the superficial temporal artery, which supplies the area of the scalp overlying the temporal region [13].

The ascending palatine artery is a branch of the facial artery, diverging soon after the facial artery branches off the ECA. It runs along the superior pharyngeal constrictor muscle and travels between the styloglossus and stylopharyngeus muscles. As it arrives at the levator veli palatini muscle it divides into two branches [13]. One continues along the pharynx to supply the palatine glands and the muscles of the soft palate, eventually anastomosing with the descending palatine branch of the maxillary artery. The other immediately pierces the pharynx to supply the palatine tonsil and auditory tube and later anastomoses with the tonsillar branch of the facial artery and the ascending pharyngeal artery [6].

The purpose of this case presentation is to discuss an anatomical variation found during a routine dissection that has important clinical implications for surgeries at the level of the angle of the mandible.

CASE PRESENTATION
During routine dissection of the right cadaveric neck of a 72-year-old at death female, multiple anatomical variations of the ECA were noted (Figs. 1 and 2). The cadaver had a history of endarterectomy of the right internal carotid. There was adhesion of the common facial vein and the hypoglossal nerve.

Lingual and facial arteries

A small branch arose from the lingual artery at the depth of the submandibular gland and bifurcated into the ascending palatine artery and a branch to the submandibular gland (Fig. 3). The ascending palatine artery ran laterally to the stylohyoid and styloglossus muscles. This is an atypical presentation, as the ascending palatine artery and the branch to the submandibular gland did not arise from the facial artery.

Ascending pharyngeal artery

The sternocleidomastoid branch arose from the ascending pharyngeal artery instead of the occipital artery (Fig. 4).

Occipital and posterior auricular arteries

The occipitoauricular trunk arose from the ECA at the level where the stylohyoid and styloglossus crossed it (Fig. 5).

DISCUSSION

Embryology of the ECA

The development of the ECA begins at weeks 3-5 in utero. The aortic sac gives rise to the aortic arches and the third aortic arch gives rise to the common carotid artery, which later bifurcates into the internal and external carotid arteries. Most branches of the ECA originate from the third arch except for the maxillary artery, which arises from the first aortic arch [5].

Other Anatomical Variations of the Branches of the ECA

There have been many studies aimed at identifying the incidences of different ECA variations. In an anatomical study of 40 cadavers, Devadas et al. identified and quantified various anatomical variations of ECA branching [4]. They observed that only 75% of their
specimens had an ECA origin at the level of the upper border of the thyroid cartilage, where it is expected. A higher-than-expected ECA origin was present in 25% cases; there were no cases with a lower-than-expected origin. It was noted that 78.75% of cases displayed separate origins for the anterior branches. On the other hand, the linguofacial trunk was seen in 16% of the specimens, making it the most commonly observed variation, while a thyrolinguofacial trunk was seen in one case (1.25%); no thyrolingual trunks were present. Notably, a case with a thyrolinguofacial trunk was also reported by Baxla et al. [1]. The ascending pharyngeal artery was normal in 97.5% of their cases, but one case (1.25%) had an unusually high origin above the carotid bifurcation, and another (1.25%) displayed double pharyngeal arteries at the posteromedial aspect of the ECA. Other notable variations were a muscular branch to the masseter muscle from the ECA in the parotid region, a slender branch to the internal jugular veins from the ECA above the superior thyroid artery origin, and a superior laryngeal artery emerging directly from the ECA in 3.75% of cases [4].

Several anatomical variations of ECA branching patterns have also been described by Navakalyani et al. [10]. In their report, the facial and lingual arteries arose from a common linguofacial trunk in 8% of cases, and the superior thyroid and the lingual arteries arose from a common thyrolinguofacial trunk in 1%. They also observed the superior thyroid artery originating from the bifurcation of the common carotid artery instead of the ECA in 8% of cases, and the ascending pharyngeal artery emerging from the occipital artery instead of the ECA in 1%. In 5% of cases there was a variation in which the posterior auricular artery branched off the occipital artery instead of branching separately off the ECA. They found no variations in the origin of the ECA, but like Devadas et al. they noted the origin at a higher level than expected in 2% of cases [10].

In a study of 302 patients, Yamamoto et al. determined the incidences of ECA branching patterns by analyzing 532 ECAs using digital subtraction angiography. They classified these arteries into three categories (A, B, C) based on the number of branches (two, three, four or more) emerging from the proximal ECA at a common point, the distal ECA counting as one branch [14]. Using this criterion, Type A (two branches) is defined as all individual branches arising separately from the proximal ECA. They observed Type A in 344 ECAs (64.6%) in 237 patients (78.5%), Type B in 134 ECAs (25.2%) in 110 patients (36.4%), and Type C in 54 ECAs (10.2%) in 49 patients (16.2%). Although Type C was the least prevalent, it had a shorter
distance (14.7 ± 6.6 mm) between the common carotid artery (CCA) and the bifurcation of the first branch of the ECA than Type A (21.8 ± 15.6 mm) or Type B (20.6 ± 8.9 mm). They also found that 96.3% of Type C ECAs had a CCA bifurcation at the level of the junction of the third-fourth cervical vertebrae or higher, which was significantly higher than the bifurcation in Type A or B. Because there are several anatomical variations, it is imperative that surgeons be aware of the Type C variation to avoid unexpected complications [14].

An anatomical variation of the ascending palatine artery, branching from the lingual artery instead of the facial artery, has been noted in previous literature. Unfortunately, we could find no more details of this variation [11].

Our present case contains several variations that have not yet been reported and are not the most commonly encountered. While variations such as the linguofacial, thyrolinguofacial, and thyrolingual trunks are gaining more exposure amongst surgeons, many others are possible. Each variant has important implications for surgeries of the head and neck such as thyroidectomies or reconstruction of a cervical aneurysm, so increasing our knowledge of these variations is imperative for reducing risks associated with head and neck surgery.

**Blood Supply to the Posterior Palate**

The ascending palatine artery provides the main source of perfusion to the soft palate, specifically supplying the uvula, palatoglossus, palatopharyngeus, and the levator veli palatini muscle. This artery splits into two branches, the anterior and the posterior ascending palatine arteries. However, some studies have shown that the two branches do not always supply the soft palate simultaneously, which could be surgically significant [3]. The ascending pharyngeal artery also has another role; it has been found to supply the palatopharyngeus muscle [7]. Other arteries to note are the lesser palatine, the palatal branch of the ascending pharyngeal, and the tonsillar, which emerge beneath the mucosal layer and anastomose with the branches of the ascending palatine artery. This rich and interconnected blood supply reduces the risk of necrosis during palatoplasty surgeries [7].

**Clinical Relevance**

The lingual and facial arteries are located in delicate regions of the head and neck, putting them at risk of causing life-threatening hemorrhages in the setting of trauma. Hemorrhages on
the floor of the mouth can obstruct the airway and require emergency tracheostomy to maintain airway patency, so anatomical variations are important for physicians to consider when they plan for surgery or treat trauma cases [9]. Although the main complication of submandibulectomies is sialadenitis, it is imperative that surgeons be wary of vessels emerging from the lingual nerve at the level of the sublingual gland [6]. In our case study, the anatomical variation of the ascending palatine vessel emerging from the lingual artery at the submandibular gland would result in necrosis of the palate if it were severed during surgery.

Anatomical variations in the arteries supplying the palate can affect the outcome of surgeries such as palatoplasty in cleft palate patients and Le Fort I osteotomies. A study of the risk of palatal necrosis in Le Fort I osteotomies showed that 90% of patients had normal anatomy in which both the ascending palatine and ascending pharyngeal arteries supplied the area, while 10% were dependent on the ascending pharyngeal artery alone for a blood supply to the palate. This reduction in vascular supply can pose a huge risk if the ascending pharyngeal artery is ligated in a patient with the variation, whereas in patients with normal anatomy the ascending palatine artery simply provides a supplement [2].

**Funding**

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors

**Acknowledgements**

The authors sincerely thank those who donated their bodies to science so that anatomical research could be performed. Results from such research can potentially increase mankind’s overall knowledge that can then improve patient care. Therefore, these donors and their families deserve our highest gratitude [8].
